Both the incidence and the mechanism of amnesia in PTSD remain controversial. One study reported that more than 30% of adults who were sexually abused as children were amnesic about the abuse for many years (Williams, 1994), but this study has been criticized on methodological grounds, and the concept of repressed memories of abuse is hotly debated (see McNally, 2003). Brewin et al. (1996) have conceptualized amnesia as the absence of verbally accessible knowledge, leaving only unconscious, situationally

accessible knowledge available. In this model, amnesia is the result of a strategy to avoid trauma-related stimuli by not attending to the negative emotions associated with the trauma. However, McNally, Metzger, Lasko, Clancy, and Pitman (1998) found that in a directed forgetting task, children with PTSD exhibited recall deficits for positive and neutral words only, as opposed to trauma-related words. Factors related to depth of encoding and retrieval, including the degree of elaboration, organization, and rehearsal of memories, may also play a role in the forgetting of unpleasant trauma-related memories (Koutstaal & Schacter, 1997).

Attention and Executive Function

Neuropsychological studies of attention in PTSD have adopted several approaches. Research in this area has examined such components of attention as sustained attention, learning of new material, shifting attention, and ideational fluency, as well as issues of attention allocation and bias.

Vasterling, Brailey, Constans, and Sutker (1998) studied Gulf War veterans with PTSD and a control group without PTSD who had also participated in combat in this war. Significant sustained attention, mental manipulation, initial acquisition of information, and retroactive interference differences were observed between the groups, as were errors of commission and intrusion. Results suggested that trauma-related intrusions may reflect a more general pattern of disinhibition. This study also found that disinhibition and intrusions on cognitive tasks correlated positively with reexperiencing symptoms and negatively with avoidance and numbing symptoms. Vasterling et al. (2002) found that Vietnam veterans with PTSD scored significantly worse than Vietnam veterans without PTSD on tasks of sustained attention, working memory, and learning, but not on focused attention or shifting attention measures. These findings were independent of intellectual functioning.

Beers and DeBellis (2002) found that children with PTSD made significantly more errors on measures of freedom from distractibility, including the Stroop Color Word Test. They also made more omission errors on a test of sustained attention. Shields and Cicchetti (1998) found attention deficits in maltreated children ages 6 to 12 relative to controls.

Studies have shown that persons with PTSD exhibit attentional biases that favor the processing of trauma-related material. Several studies employing word list-learning tasks with trauma-related and neutral words have shown that Vietnam veterans with PTSD exhibit an enhancement of implicit memory for words related to the trauma versus control subjects (Amir, Kaplan, & Kotler, 1996; Zeitlin & McNally, 1991). Emotional Stroop tasks use emotionally

laden words related to the trauma (i.e., body bag), interspersed with nonemotional words. Words are printed in different colors and participants must name the ink color and suppress the prepotent tendency to read the words. Studies employing these paradigms have found that PTSD patients have an attentional bias to trauma-related words, resulting in an enhanced Stroop effect (greater interference of word reading on color naming). This has been shown for Vietnam veterans (McNally, Kaspi, Riemann, & Zeitlin, 1990), rape and sexual abuse victims (Bremner et al., 2004; Foa, Feske, Murdock, Kozak, & McCarthy, 1991), and survivors of motor vehicle accidents (Bryant & Harvey, 1997). Stroop interference for words related to trauma appears to be correlated with the severity of the PTSD symptoms as assessed by standardized measures (McNally et al., 1990) and self-reports (Cassidy, McNally, & Zeitlin, 1992). It has been suggested that reduced capacities to inhibit unwanted or situationally inappropriate information may cause individuals with PTSD to have difficulty focusing, particularly under stressful or novel conditions (Weinstein, Fucetola, & Mollica, 2001).

Koenen et al. (2001) studied 16 patients with PTSD (primarily women) and 53 neurologically intact control subjects (primarily men ages 20 to 64). Patients with PTSD were significantly more impaired on delayed alternation, object alternation, and delayed nonmatch-to-sample tasks, suggesting overlapping deficits in dorsolateral and orbital regions of the prefrontal cortex. Beers and DeBellis (2002) found that on the Wisconsin Card Sorting Task (Heaton, Chelune, Talley, Kay, & Curtiss, 1993) subjects with PTSD completed fewer categories than control subjects. These authors also showed that ideational fluency in children with PTSD, as assessed by the animal naming and FAS tasks, was compromised. Another study of children ages 11 to 17 with PTSD found significantly lower performance than controls on measures of planning and cognitive flexibility (Moradi et al., 1999).

Social Cognition

Research on social cognition in children with PTSD emanates primarily from work on child maltreatment. Several early studies demonstrated that maltreated children show atypical patterns of emotion expression and recognition relative to children who have not been maltreated (Camras et al., 1990; Gaensbauer & Hiatt, 1984). More recent studies have converged in finding that maltreated children have particular difficulty interpreting anger. Pollak, Cicchetti, Hornung, and Reed (2000) found that, compared with control children, physically abused preschoolers had a response bias toward incorrect interpretation of anger when

presented with brief emotional stories and asked to match the feeling of the protagonist with a photograph of a model posing with a facial expression. They also found that physically abused and neglected children generally detected fewer differences between facial expressions than did children in the control group. Pollak, Cicchetti, Klorman, and Brumaghim (1997) conducted an event-related brain potential study and found that, compared to control children, children with maltreatment histories had larger P3b amplitudes when shown angry versus happy and neutral faces. A later study failed to find increased P3b amplitudes to fearful faces (Pollak, Klorman, Thatcher, & Cicchetti, 2001). This suggests that maltreated children may allocate greater attentional resources to angry faces than to other expressions of emotion.

In summation, existing studies of the neuropsychology of PTSD suggest that it involves general deficits in short-term memory, sustained attention, working memory, learning, inhibition, and comprehension and expression of emotions. These deficits appear to be exacerbated by exposure to emotional stimuli reminiscent of the trauma. Individuals with PTSD attend to information in atypical and distorted ways. Trauma-related materials both heighten and dampen arousal levels; some aspects of memory are impaired and others are accentuated.

Neuropsychological Models

We now turn to a discussion of the conceptual neuropsychological models that have been used to explain PTSD and explore their ability to account for these empirical findings.

Classical Conditioning Models. PTSD has been conceptualized as a case of classical conditioning (see Barlow, 1988; Pitman et al., 1999). In the classical conditioning model, the traumatic stimulus (unconditioned stimulus) has induced an intense unpleasant reaction of fear, helplessness, or horror (unconditioned response). External and internal cues present at the time of this trauma (conditioned stimuli) become paired with the traumatic experience and evoke intense emotional responses on future occasions (conditioned responses). This results in fearful reexperiencing symptoms associated with the original trauma. As mentioned earlier, this type of fear conditioning, which is hypothesized to involve the limbic system, especially the amygdala, is thought to be involved in other anxiety disorders, including Panic Disorder and phobias (LeDoux, 2002). So what began as a purely psychological construct as part of the behaviorist paradigm has now become a neuropsychological construct as the underlying brain mechanisms have been understood. As we will see, this conditioning theory of PTSD needs to be

broadened to account for individual differences in susceptibility to PTSD, the developmental trajectory of PTSD, other symptoms of PTSD, such as numbing and trauma-related amnesia, and other neuropsychological deficits associated with PTSD, such as impairments in attention and declarative memory.

Extinction and sensitization, two other processes related to fear conditioning, are important for explaining PTSD. To explain these phenomena, brain-level findings must be considered in combination with conceptual neuropsychological models. In PTSD, there is likely a sensitization process whereby repetitive exposure to stimuli elevates the sensitivity of limbic system networks, reduces extinction of the conditioned fear, and/or causes sensitization of the HPA axis. PTSD sufferers also avoid reminders of the trauma, thus robbing themselves of new learning opportunities that would extinguish fear conditioning. Thus, the fear conditioning model can explain many PTSD symptoms, including reexperiencing, avoidance, and high arousal. It does not, however, account for all *DSM* symptoms, including numbing, feelings of estrangement, and a sense of a foreshortened future. Similarly, the classical conditioning model does not offer insights as to why some people are more likely than others to develop PTSD symptoms and why symptom severity levels differ. As mentioned earlier, it is hypothesized that certain etiological factors may result in increased vulnerability to acute stress reactions, but these are not part of the fear conditioning model.

Similarly, genetic and brain-level findings need to be used in concert with neuropsychological findings in explaining PTSD comorbidities. Classical conditioning models do not account for the common co-occurrence of depression with PTSD, for example, but HPA axis dysregulation and limbic system abnormalities may explain comorbidities. Disruptions in different parts of these circuits might lead to one or a combination of disorders.

In addition, the classical conditioning model does not offer a way to think about the developmental trajectory of PTSD or developmental discontinuities in PTSD symptoms. It does not explain trauma-related amnesia. Furthermore, it does not predict the declarative memory, sustained attention, and learning deficits found in the empirical research reviewed earlier. In sum, fear conditioning may indeed lie at the heart of PTSD, but the classical conditioning model needs to be broadened to account for individual differences, developmental differences, and other features of PTSD.

Cognitive-Behavioral/Information-Processing Models. Cognitive-behavioral/information-processing

models build on the concept of fear conditioning but further propose that traumatic experiences strengthen connections among distributed cognitive, behavioral, and physiological memory representations related to the trauma (see Foa & Kozak, 1986). Activation of any part of the trauma memory network can reactivate the whole structure. When an input to the system matches the emotional memory network (e.g., the noise of a gunshot), it is reactivated, and the trauma response is reexperienced in the form of arousal, vivid and intrusive memories, and fear. Traumas themselves are forms of powerful but discrepant information that is not easily assimilated into existing cognitive schemata for the way the world works (Brewin et al., 1996; Foa, Steketee, & Rothbaum, 1989). As a result of trauma exposure, PTSD patients develop serious perceptual distortions in the way they process information. Arousal also results: Traumas are believed to involve unpleasant and excessive arousal. The individual avoids trauma cues: Avoidance prevents new learning so that new and more inclusive schemata can be formed.

Brewin et al. (1996) proposed a dual representation model that differentiates conscious and unconscious processes. In this model, both conscious and unconscious information is accessed automatically when physical features or meanings in the current situation resemble those of the trauma. Attentional and memory processes favor trauma-related information over neutral information, perpetuating the experiencing of traumatic information.

Cognitive-behavioral models provide explanations for the major clusters of PTSD symptoms. Reexperiencing is seen as a result of memory network activation when there is a match between existing cognitive schemata and the environment. This is especially problematic because attention and memory are believed to favor trauma-related information. Avoidance is viewed as the strategy used by the individual to prevent confrontation with reexposure to cues. Arousal is seen as an element of the traumatic memory network and part of the experience of discrepant horrific information. Memories can be activated without conscious awareness.

One of the major advantages of cognitive-behavioral/information-processing models of PTSD is that they allow more room for considering the role of cognition in the development of symptoms than do classical conditioning paradigms. This type of memory network model also is consistent with empirical findings suggesting that trauma-related stimuli are overwhelming and affect learning and memory. Although these models do not provide an explanation for who develops symptoms, they do provide a means of explaining why some PTSD symptoms are worse than

others based on the size and interconnectivity of the cognitive, behavioral, and physiologic components of the trauma-related memory structure. Cognitive-behavioral/information-processing models also are more able to include a developmental dimension as they can incorporate information about age-graded development in cognitions that trigger symptoms (Pynoos et al., 1999). This enables one to make predictions about the course of PTSD symptoms and about the likelihood of developing trauma symptoms at different points in the life course.

Cognitive-behavioral/information-processing models have their limitations, however. They do not explain why certain disorders are comorbid with PTSD. They do not explain why depression, which may also involve a traumatic precipitant, has symptoms distinct from PTSD. Similarly, these models provide no explanation for general short-term memory problems or amnesia.

Neural Network Models. Over the past 15 years, various researchers have employed neural network models to develop insight into how the brain processes information. Rumelhart, McClelland, and the Parallel Distributed Processing Group (1986) were among the first to attempt to model the microstructure of cognition with greater fidelity to brain structures and processes. Pitman and Orr (1990) were the first to use network models to enhance the understanding of PTSD.

Network theory simultaneously considers the structure created by multiple stimulus-response pairs. There is no executive process in the network. Instead, elements of the network are dynamically interdependent: The activation of one element enhances the activation of all others with which it is positively connected and diminishes the activation of all other elements with which it is negatively connected. Relationships between the nodes in the network are frequently nonlinear. This means that a small change in one processing node can create large changes in others. The term "spreading activation" is used to describe the process whereby one portion of the network influences others. Most recent models used to describe PTSD are connectionist models, meaning that all nodes and layers of the network are connected to one another.

Network models allow one to model the complex elements of a fear structure, including emotional processes (see Tryon, 1999, for a description of a bidirectional associative memory explanation of PTSD). Fear can be understood as a structure in the memory network that contains information about external stimuli, as well as verbal and nonverbal reactions to their meanings. Connections between the parts of the network are both excitatory and inhibitory and mediate

psychophysiological responses to script-driven imagery and to escape and avoidance behavior. In this kind of a network, short-term, within-session habituation is thought to evoke a change in the fear structure. The reduction of arousal in the presence of fear cues causes new memories. (This is thought to be the mechanism through which systematic desensitization occurs.) Other disorders and typical fears involve memory structures, but in PTSD the network responses are more ready, intense, large, and easily accessible.

Pitman and Orr (1990) and Tryon (1999) suggested that networks for memories are created through memory “wells” in a flat memory surface (i.e., attractors in a multi-dimensional space). A visual representation of such a model is a rubber sheet held taut with a ball bearing placed on it; the indentation made by the ball bearing is the memory well. These wells are attractors because another ball bearing placed on the sheet would roll to the indentation. PTSD memories are thought to create similar “basins of attraction.” Normal memory formation also involves the creation of wells. In PTSD, abnormally deep and attractive basins are formed, as if a heavier ball bearing were placed on the rubber sheet, thereby drawing multiple stimuli into the well. The traumatic incident warps the gradient of memory recall such that previously innocuous stimuli roll into the superbasin of the trauma memory well. The gradient becomes so warped that it incorporates stimuli relating to other memories. Network models also have a drive toward pattern completion, meaning that once activation is initiated, it spreads throughout the network.

Such theoretical neural network models offer potential explanations for many PTSD symptoms, although they have yet to be empirically tested. Reexperiencing symptoms may be explained by the warped gradient of memory retrieval that incorporates unrelated and irrelevant stimuli and memories. Emotional numbing and other avoidance-related phenomena could occur when the person tries to prevent pattern completion by avoiding the emotional states capable of triggering the memory recall. Arousal symptoms may occur because of pattern completion tendencies and because even partial cues trigger recall.

Several novel predictions can be made from this neural network model. First, quality and duration of memory recall, as well as efficiency of pattern completion, are hypothesized to correlate with the severity of PTSD symptoms because activation will spread through the network more widely, efficiently, and quickly. This can be extended to suggest that some individuals have a genetic predisposition to process information and complete patterns rapidly, and this may be disadvantageous if they are exposed to trauma. Second, state-dependent memory ef-

fects are proposed to be operating because emotions are coded with cognitions. For example, fearful memories are more likely to be recalled when the person is frightened versus happy. Emotions participate equally with cognitions in facilitating recall. Entire memories can be retrieved by purely cognitive or purely emotional cues. A third prediction of neural network models is that logical reciprocal inhibition should be operative; thus, there may be some equally strong memories capable of inhibiting trauma-related ones. Finally, persons with more severe PTSD will have fear structures with broader associative structures. The associative structures can be mapped, studied, and used therapeutically. These predictions have yet to be tested.

In conclusion, the neuropsychology of PTSD is relatively well understood, albeit not as extensive as that of Autism, where the symptom profile is broader and thus there is more to explain. However, there are still opportunities to replicate existing studies of PTSD and design new ones that deepen our understanding of memory, learning, attention, and executive functions in this disorder. Relatively little is known, for example, about traumatic amnesia and numbing. Neuropsychological studies also may provide useful information about individual differences in vulnerability to PTSD, symptom profiles, symptom severity, and developed fear structures after a traumatic event.

The neuropsychological models described here also raise interesting issues about treatment matching. In particular, the neural network model provides several novel ideas about constructs that may be useful to study and then employ in PTSD interventions. First, it may be fruitful to better understand and measure a variable assessing ease of pattern completion and spreading activation, as these constructs may be related to who develops PTSD, symptom severity, and how to “cure” the disorder. Second, studies of the existence of logical reciprocal inhibition may help shrink traumatic memory structures or wells and provide additional clues for treatments. Finally, through careful mapping of individual fear structures, it may be possible to develop individually tailored exposure or information-processing therapies that help reduce the hold of traumatic memories.

“RETROFITTING THE BRIDGE”: LIMITATIONS OF AND FUTURE DIRECTIONS FOR THE NEUROSCIENTIFIC MODEL

In earlier papers, we made a plea for parsimony (Pennington & Ozonoff, 1991). We suggested that initial neuroscientific models of developmental psychopathologies, as we

moved from the atheoretical descriptive stage to an understanding of the three deeper levels of analysis, should be simple. That is, we should propose complexity only as the model demonstrates the need for it. This was an appropriate starting point for an emerging developmental science, but it is now time to reevaluate the simpler models put forth in this chapter to see how far they have taken us. In the preceding discussions of Autism and PTSD, we highlighted both the strengths and the limitations of the neuropsychological models relevant to each condition. In each case, but to differing degrees, extant models have not adequately accounted for the complexities of these developmental psychopathologies. In this final section, we explore how they have broken down and how the limitations they expose may help us improve future neuropsychological models of developmental psychopathology.

Revisiting the Promise of the Neuropsychological Level

At the outset of this chapter, we suggested that the neuropsychological level provided an important bridge between biology and behavior. We maintain the point that some functional bridge that translates brain dysfunction to behavioral symptoms is necessary. We have chosen to call this bridge “neuropsychology,” but it is possible that this term has itself become reified. That is, what is really required at the bridging level is some computational algorithm, some translation of inputs to output, but this bridge may or may not be best conceptualized through the traditional domains of neuropsychology. For an alternative account of this bridging level, we summarize the model of David Marr (1982), an influential visual scientist, who proposed three interdependent levels in cognitive science: (1) a computational level, (2) an algorithmic level, and (3) an implementation level. The *computational* level is Marr’s highest level (that most related to observed behavior) and is concerned with characterizing the function or goal of a particular piece of information processing or input-output mapping (e.g., stereopsis, printed word recognition, face recognition). A computational theory provides a formal account of the nature of the inputs and outputs and the mapping between them in a particular cognitive computation and incorporates what we know about real-world constraints on that computation. For many of the functions relevant for understanding psychopathology (e.g., emotion perception, mood regulation), we currently lack adequate theories even at this highest computational level.

The next level in Marr’s (1982) framework is the *algorithm*, which concerns how a particular mapping is actually

computed and must specify the nature of the input and output representations and the actual mathematical algorithm for computing an output from an input. A connectionist or parallel distributed processing model, which computes the mapping from input to output in a given domain, is an example of the algorithm level. The third and lowest (or most internal) level is that of *implementation* and is concerned with how these representations and algorithms are realized in the physical system of the brain.

How do the levels in the neuroscientific framework we have proposed in this chapter map onto Marr’s (1982) levels? Basically, our symptom level would correspond to the behavioral phenomenon (e.g., stereopsis) that Marr’s levels are intended to explain; this behavioral level is not an explicit level in Marr’s model. The computational and algorithmic levels together roughly equal the neuropsychological level in our framework. In seeking the primary neuropsychological deficit(s) in a given psychopathology, we are testing theories of which particular input-output mappings are impaired, with the long-term goal of providing an algorithmic or neurocomputational account of this deficit and how it explains the symptoms that define the disorder. Marr’s implementation level corresponds to our brain level. Finally, because Marr did not aspire to explain individual differences, he did not need an etiological level. But of course, this level is key in any explanation of a psychopathology, which must account for why some people are more at risk for a given disorder than others.

It is hard to imagine that we could ever dispense with a bridging level, whether Marr’s (1982) computational level, our neuropsychological level, or some other, in an explanation of normal and abnormal behavior. Even if we had complete accounts of etiologies and symptoms, we would still want a functional account of how one is translated into the other. So, although it is important not to reify the neuropsychological level, it appears necessary to the mature accounts of all psychopathological disorders.

One implication of Marr’s (1982) approach and ours is that these levels are logically and causally related and that progress at one level will change our understanding at another. This is an example of the network theory of scientific truth in action. Terms and concepts at each level of analysis are not in tight compartments; rather, their meaning changes as we learn more about other levels of analysis. For instance, the language of symptoms is not theory-neutral. Instead, which symptoms are highlighted in the definition of a disorder and how they are defined changes as we understand more about other levels of analysis. The same applies to the other levels of analysis. A purely psychological construct, such as classical conditioning of the fear response, takes on

different meanings as we understand more about the neural implementation of fear conditioning in the amygdala and other structures. Similarly, the meaning of symptoms of anxiety disorders will also change with this increased understanding, as will which genetic or environmental risk factors are considered candidates for understanding individual differences in anxiety. So, as you read our reviews of Autism and PTSD, you may have noticed that it was sometimes hard to decide which level a particular finding belonged to. How would we classify a finding of heightened amygdala activity in response to angry faces in individuals with a particular allele of the serotonin transporter gene? Obviously, it belongs to three, if not all four levels of analysis.

A closely related point is that methods that bridge levels of analysis are particularly informative. Functional neuroimaging studies, including fMRI and ERP studies, by definition bridge at least two levels of analysis, and when applied to psychopathology, include three: symptoms, cognition, and brain function. Behavioral and molecular genetic studies of psychopathology bridge at least two levels of analysis, etiology and symptoms, and potentially three (if cognitive measures are added) or even four (if the study also includes functional neuroimaging). An integrated explanation of a given developmental psychopathology will require converging findings across levels of analysis.

The *Diagnostic and Statistical Manual of Mental Disorders* is described as an atheoretical taxonomy, based largely on the symptom level of analysis. A more pathogenesis-driven classification system would look considerably different (Pennington, 2002). For example, PTSD could be categorized as a disorder of HPA dysregulation along with other anxiety disorders (a combination etiological-level and brain-level explanation), a disorder of hippocampal pathology due to excess glucocorticoids like Cushing's disease or Schizophrenia (an alternative brain-level explanation), a disorder of unfortunate conditioning of the limbic system's fear circuits like Panic Disorder (more of a neuropsychology explanation), or a disorder of Luria's arousal motivation system along with other anxiety disorders and Bipolar Disorder (an alternative neuropsychological conception). We do not yet know which conceptualization will turn out to be most useful; neuropsychology may be part of the answer, but not the whole answer.

Modules or Networks? Single or Multiple Deficits?

Another limitation of neuropsychological models that has been readily recognized for many years is their modularity

(e.g., Karmiloff-Smith, 1992). As discussed earlier in this chapter, the most familiar and traditional approach to linking behavior to brain mechanisms is the lesion model, derived from the study of (usually adult) patients with acquired brain insults. This model infers that the injured regions control the functions that are deficient postinjury and, by analogy to the normal brain, attributes specific cognitive functions to distinct brain regions. This model is a simplification that has worked in many ways, launching the fields of experimental cognitive science and neuroscience (Finger, 1994). Decades of elegant experiments have confirmed, in broad strokes, that particular brain regions are indeed involved in particular cognitive functions. For example, there is little doubt that the temporal cortex of the dominant hemisphere is specialized for producing and comprehending language (Dick et al., 2001). It is also clear, however, that multiple additional brain regions are active during language-related tasks.

Just as typical neuropsychological development involves complex, dynamic, distributed neural systems, so, too, does atypical neuropsychological development (Oliver, Johnson, Karmiloff-Smith, & Pennington, 2000). Thus, it is unlikely that any one neuropsychological deficit or damage to any one brain region could explain all manifestations of complex syndromes like Autism or PTSD. Many different theories of Autism are based on modular conceptualizations of neuropsychological function, from the executive dysfunction theory (Russell, 1997), to Leslie's (1992) theory of mind module, to the recent amygdala theory of Autism (Baron-Cohen et al., 2000). It is likely that each of these (and other) theories will turn out to be only partial models that explain some, but not all, features of Autism. There appear to be a number of interacting genes, as well as other unknown nongenetic factors, required for development of the disorder. It is unlikely that each of these etiologic risks would operate on the same functional neuropsychological (or neural) system, making a single deficit model both biologically and theoretically implausible. Indeed, it is unlikely that genes have specific effects on regions of the cortex or cognitive functions, but affect brain development in a general way (Shatz, 1992).

Similarly, dysfunction of a single neuropsychological module cannot explain the wide variation in abilities and deficits that are part of Autism, nor the continuum of severity from higher functioning to seriously disabled. During development, many paths lead to the same end (equifinality), and the same causes can have different outcomes (multifinality; Cicchetti & Rogosch, 1996). This is incompatible with single primary deficit accounts of developmental psy-

chopathologies (Yeung-Courchesne & Courchesne, 1997). Focus on unitary mechanisms, at whatever level, is inappropriate for a complex phenotype.

Developmental Issues

It must be admitted that early (and even current) applications of a neuropsychological approach to disorders in children have often lacked a developmental perspective. For instance, more than 100 years ago, Hinshelwood (1896) explained developmental dyslexia as “congenital word blindness” and postulated abnormal development of the left angular gyrus as the cause. His theory was based on the discovery by Dejerine that a form of acquired dyslexia in adults followed damage to that brain structure. This theory ignores development on two counts. First, it assumes that the same structure serves reading in both children and adults. Second, it comes close to assuming that there is an innate brain center for a function that could not have evolved! Obviously, any reading “centers” in the brain must emerge as a result of instruction and experience. Explaining Autism as congenital mind blindness commits some of these same conceptual errors. Even though theory of mind, unlike reading, did evolve, it is very unlikely to be innate or localized.

The implicit assumption has often been that brain-behavior relations are static across development and hence similar in adults and children. Therefore, the same constructs and even measures could be used across ages. In this “static neuropsychological deficit” approach to understanding developmental disorders, it is further assumed that a mapping exists between damage to or dysfunction in a localized brain structure and a particular cognitive deficit, and that cause runs from the neural to the cognitive level (Oliver et al., 2000). As a consequence of these assumptions, such disorders have often been studied at later ages, close to their developmental end state. As discussed by Oliver et al., recent findings in developmental neuroscience have questioned these core assumptions of the static neuropsychological approach and call for a radically different approach to understanding brain-behavior interactions in both developmental disorders and the mature brain. In this alternative neuroconstructionist or connectionist approach, the specializations found in the mature brain are *products* of development rather than innate, prewired modules. Atypical development results from subtle, often widespread, differences in the initial state which lead to “alternative developmental trajectories in the emergence of representations within neural networks” (p. 1). It follows

that the neuropsychological phenotype observed in a given developmental disorder will change with age and that the mapping from the initial to the final state will be complex.

Broca himself noted that lesions resulting in aphasia in adults do not usually prevent children from learning to talk (Moses & Stiles, 2002). Traditional neuropsychological models that ascribe language functions to the left temporal cortex do not explain this phenomenon, just as the neuropsychological model of Autism discussed in this chapter had very little to say about plasticity and resilience. No explanations are provided for the remarkable progress that is sometimes evident after intensive early intervention (Lovaas, 1987). Attributing Autism to a defect in the theory of mind module (Leslie, 1992), as just one example, does not help us understand why some children fare so well with early treatment and what changes in cortical organization take place during intervention. Functional brain imaging studies have pointed to different patterns of activation during task performance in individuals with Autism. Do these differences indicate dysfunction or plasticity (or perhaps both)? What are the limitations to plasticity? Such questions are impossible to answer until the field of developmental neuroscience matures and we know more about typical patterns of brain activation across development.

The Role of Emotion and Related Constructs

One conclusion of this chapter is that the traditional list of neuropsychological domains is not sufficient to account for psychopathology. We need to broaden the list; once we do, it will include many psychological constructs not traditionally considered neuropsychological (e.g., emotion) and not nearly as well understood or studied as the domains of memory and attention. There is a clear need for better neuropsychological models of motivation, emotion regulation, and social cognition. Neuropsychological models of Autism have been difficult to build without a good theory of normal social cognitive and emotional development or a clear understanding of the neural networks that subservise it. Many forms of psychopathology involve dysregulated emotional states and/or deficient social cognitive abilities, yet there are few standardized or naturalistic measures of these processes and little exploration of their role in psychopathology. Even research on affective disorders has, until recently, shed little light on precisely what is disordered about emotion in these conditions (Davidson, 1998). Some recent attempts to integrate emotion and neuropsychological performance can be seen in the PTSD field, where emotional Stroop tasks have been used to explore processing of

emotionally charged versus emotionally neutral stimuli. Recent research on individuals with Bipolar Disorder has examined emotional state-dependent recall (Murphy & Sahakian, 2001). Neuroimaging studies are beginning to illuminate the types of brain changes that accompany the experience of emotional states (Damasio et al., 2000). Psychophysiological measures also hold promise for assessing arousal levels that are constituent parts of emotions, and it has been suggested that emotional arousal influences memory encoding and consolidation (Hamann, 2001). Future work should continue down these exciting paths.

Temperament is another area that is critical to consider when assessing psychopathology and neuropsychological functioning. Some recent and innovative research programs have attempted to integrate findings from the diverse fields of temperament research, neuropsychology, and neuroimaging (see Posner, 2002). For example, it has been suggested that it is necessary to study components of temperament to understand individual differences in the development of attentional networks in early childhood (Rothbart & Posner, 2001). Effortful control is one temperamental variable related to the development of executive attention. Studies have shown it to be positively associated with the development of conscience (Kochanska, Murray, & Coy, 1997) and empathy (Rothbart, Ahadi, & Hershey, 1994) and inversely correlated with negative affect. In this view, the development of attentional networks and the development of emotional self-regulation are inextricably linked and must be studied in an integrated way.

A third area of social cognition that is rarely considered in neuropsychological research on developmental psychopathology is the role of individual differences in attribution style and perception of the environment. This is critical in a disorder like PTSD, where an individual's perceptions of a traumatic stimulus can influence symptom severity and mediate outcome. Yet there is little systematic research in this area.

CONCLUSION

We have come a long way in the 40 years or so that the neuropsychological model has been applied to better understand the bases of child psychopathologies. Not long ago, most forms of psychopathology were considered social-interpersonal in origin; now, it is clear that most involve some form of brain difference, regardless of whether the etiological mechanisms are environmental or biological. Research at the neuropsychological level of analysis was important to this realization. Early studies administered traditional

neuropsychological batteries to children with psychopathology and found that even those with social-environmental etiologies displayed distinct impairments. The limits of this approach have become apparent over time, and it is no longer terribly informative to document that a particular form of psychopathology is associated with a particular neuropsychological deficit or deficits. We argue that the neuropsychological perspective is nevertheless critical as a computational bridge or heuristic for explaining how genes, neurotransmitters, and specific patterns of brain activation are displayed as symptoms. Now is an exciting time to be a developmental psychopathologist, as the emerging ability to image the living brain at work and computationally model its inputs and outputs may ultimately open what was once a black box.

Psychophysiology may be defined as that area of research examining the interaction of physiological systems and psychological states. It involves both the measurement of reactions of a physiological system to changes in psychological state and the influence of a physiological system on the initiation, presentation, and termination of psychological behavior. In this sense, psychophysiology is truly bidirectional, involving both input and output systems that guide, reflect, and accompany psychological behavior. A good example of this can be seen in work indicating that prolonged exposure to abuse and maltreatment can reshape the functioning of core regulatory systems (Cicchetti & Rogosch, 2001; Glaser, 2000; Hart, Gunnar, & Cicchetti, 1995). It appears that along with behavioral and psychological systems, central physiological mechanisms will also reorganize to maximally adapt to the demands of the environment (Campos, Campos, & Barrett, 1989), however aberrant. It is because of this bidirectional relationship that developmental psychophysiology holds great promise for the study of developmental psychopathology.

Developmental psychophysiology also holds the promise of helping the field expand its research boundaries to incorporate multiple levels of analyses. For example, Sroufe and Rutter (1984) contend that developmental psychopathology should emphasize four broad areas of study: (1) the origins and time course of early appearing psychopathology, (2) the varying manifestations of disorder with development, (3) the precursors and sequelae of these disorders, and (4) the relationship of maladaptation to nondisordered patterns of behavior. To do so, researchers must be able to examine and compare developmental processes that act and interact at the behavioral, cognitive, affective, and psychophysiological levels. In this way, researchers can build a multidimensional model of the mechanisms and manifestations of developmental psychopathology.

For example, in assessing risk, Cicchetti and Dawson (2002) note that risk factors can appear at varying levels, ranging from the molecular to the environmental. Although any single risk factor may not be sufficient for a disorder to

manifest, the collective risk found in the pooling of vulnerabilities across levels of functioning may lead to the larger overarching disorders described clinically. In addition, because risk factors tend to act synergistically rather than additively and are rarely found in isolation (Cicchetti & Dawson, 2002), the use of multiple levels of analysis is also critical to outlining the bidirectional nature of the physiology-behavioral link (Kagan, Snidman, McManis, Woodward, & Hardway, 2002).

However, out of either necessity or long-standing tradition, researchers often treat psychopathology as a binary system. That is, participants in studies are often divided into two exclusive groups that are labeled disordered and nondisordered. Our schemes for categorizing and diagnosing psychopathology are dependent on documenting a compendium of behaviors, affects, and cognitions that are both highly variable and dynamic in nature. Indeed, even in the case of developmental disorders with clear genetic markers, such as Down syndrome and Fragile X, the path between genotype and phenotype is so complex that a simple karyotype tells us very little about the psychological state of the individual in question. Therefore, one of the main goals for developmental psychopathology has been to create more precise and nuanced profiles of individual developmental disorders, incorporating both observed behavior and underlying developmental mechanisms. In the past 2 decades, psychophysiological measures have become a central tool in this endeavor.

The increasing use of developmental psychophysiology in developmental psychopathology research has evolved from the unique strengths of the psychophysiological approach and the insights it allows into the processes underlying or accompanying early maladaptation. Inherent in the developmental psychopathological approach is the study of the manner in which early dispositions lead to adaptations in psychological behavior over time. Trajectories of human development are an outgrowth of the interaction between a given nervous system's readiness and reactivity and the adaptations of that nervous system across time. Behavioral change is a result of initial dispositions responding to dynamic and challenging environmental contexts. Research involving measurement of physiological systems thus holds great promise for elucidating important aspects of the bidirectional influences on individual trajectories across development.

In this chapter, we start with the basic tenets and strengths of psychophysiological research. We then systematically examine and review research exploring a variety of physiological systems, detailing issues of approach and measurement. We end this chapter with some thoughts on the fu-

ture directions of this type of research for the field of developmental psychopathology.

STRENGTHS OF THE PSYCHOPHYSIOLOGICAL APPROACH

The use of physiological measures in behavioral research provides a number of advantages, permitting a window onto the bidirectional influence that physiological systems have on behavior and behavior on physiology. However, it is important to note that psychophysiology does not convey a special truth to data independent of behavior. Often, investigators will claim that physiological responses are more objective than behavioral analysis. In fact, such measures are no more essential than precise behavioral measurement. As van der Molen and Molenaar (1994, p. 466) noted, "The usefulness of psychophysiological measures depends on the demonstration of the sensitivity of the measures to task manipulations derived from developmental psychology." Psychophysiology does provide, however, a means for understanding a level of processing that may not be accessible through observation alone.

Psychophysiology illuminates the link between physiology and behavior, opening up the possibility of supplementing behavioral classifications with the structure, function, and timing of underlying physiological and neural events. Psychophysiology also allows developmental researchers to incorporate a multiple-measures approach, giving them an ability to create multidimensional profiles of the areas of interest and examine associations and disassociations between physiology and behavior. Finally, this approach is exceedingly useful for preverbal and compromised populations, which are often at the heart of developmental psychopathology.

Understanding the Physiology-Behavior Connection

A major strength of the psychophysiological approach is that one can examine the action of a targeted physiological system as it changes in response to psychological challenge. The nature of that change, the manner in which physiological change energizes, arouses, or inhibits behavior, may provide insight into psychological responses to challenge. Knowledge of the underlying physiology of that system as well as an understanding of what aspects of that system are being reflected in its measurement is critical if accurate interpretation of the change in physiology is to be made. At a very basic level, it is important to understand how the physiological system works, that is, how it activates or inhibits behavior. Similarly, it is crucial to understand which mea-

tures of a particular physiological system best reflect these processes.

For many years, for example, heart rate increases in mobile infants who were exposed to unfamiliar adults were assumed to reflect the state of fear in the infants. Infants were approached by an unfamiliar adult while researchers monitored cardiac activity. Increases in heart rate were thought to reflect the infant's fear of the stranger. Increases and decreases in heart rate, however, are multiply determined. Heart rate change could be the result of metabolic, motor, or psychological change or some combination thereof. Infants who actively moved in response to stranger approach would show heart rate increases, as would an infant who would sit still and cry during this situation. Heart rate increases could not differentiate among these different behavioral responses. The lack of specificity of the physiological response and the multidetermined nature of the response raise important caveats in interpreting heart rate changes during certain types of challenge. Often, however, researchers fall back on the presumed psychological explanation for heart rate change (e.g., arousal, fear, anxiety) without first examining other potential confounding influences.

Linking multidetermined physiological responses to diffuse and nonspecific psychological states (e.g., arousal or anxiety) leads to a lack of precision in the association between the physiological change and the psychological state. This lack of precision in identifying the physiological factors involved in the increased heart rate and the lack of precision in the definition of the underlying psychological state do not facilitate further understanding of the phenomenon of interest. Thus, the very strength of the psychophysiological approach, linking physiological and behavioral change, may sometimes be a critical weakness, particularly when the underlying physiological processes are not well understood.

On the other hand, there are examples from the psychophysiology literature in which knowledge of physiological mechanisms assists in the interpretation of behavioral change. Porges (Porges & Byrne, 1992) has shown that by using complex filtering and statistical techniques, one can identify and extract the component of heart rate, reflecting parasympathetic influence. Vagal tone is a quantification of the variability in heart rate due to respiratory influences that are primarily vagal in origin. The level of vagal tone of an individual or changes in vagal tone as a result of psychological challenge may be interpreted as reflecting the influence of parasympathetic tone or vagal activity on heart rate. The obvious benefit of such precision is that it allows one to examine the relationship of this system to both higher cortical responses and other connected peripheral responses. For example, one can map out the manner in which changes

in vagal tone affect brain stem nuclei and upstream cortical centers that may modulate attention. Similarly, one can examine the influence of cortical regions on the brain stem nuclei, which control parasympathetic tone. In addition, because vagus nerve activity affects multiple organ sites, one can begin to describe the manner in which individual differences in vagal tone affect physiological and psychological organization and preparedness for action and behavior. Finally, the precision of physiological description and links to specific psychological behaviors allows one to develop models for how certain initial dispositions may adapt to changing environmental challenges.

Assessing Function through the Timing of Physiological Change

Yet another strength of the psychophysiological approach can be found in its ability to reflect the importance of timing of physiological events underlying or accompanying behavior. Each physiological system commonly measured in psychophysiological research has its distinct time course, which affects and is affected by psychological challenge and behavioral response. For example, recording brain electrical activity (i.e., electroencephalogram, EEG) during repeated stimulus presentation allows the creation of event-related potentials (ERPs), which reflect the timing of neural processing. These ERPs may reflect the immediate processing of sensory information at the millisecond level as well as higher-order cortical processing at the level of hundreds of milliseconds. Continuing the time line, measures of the autonomic nervous system (e.g., heart rate) provide information at the level of seconds, and activity in the limbic-hypothalamic-pituitary-adrenal (LHPA) axis is at the level of minutes. The varying time course for different physiological systems directly reflects their function in the individual's response to psychological challenge, be it to evaluate the stimulus (milliseconds), divert resources such as blood and oxygen to muscle to respond (seconds), or organize a response to provide energy toward restoring homeostasis in the body (minutes). The timing of physiological responses links directly to the behaviors under study and may provide insight into the function of the behavior in response to the particular challenge.

Providing Multidimensional Biobehavioral Profiles

The use of multiple measures applied to experimental settings allows for a richer and more nuanced analysis of data, particularly when interested in performance differences across two or more groups. A central strategy in

developmental psychopathology research is to contrast the performance of a clinical or high-risk group on a particular task with that of a healthy control group. The addition of multiple measures allows for the addition of analyses that focus on individual differences across two or more physiological systems, which are often both theoretically and statistically stronger avenues for discovery. Perhaps as important, researchers can now look to between-group differences in within-group response patterns. This allows for the examination of individual and group profiles, which may produce a more stable or informative picture of a given disorder than would isolated bits of data. This is in line with the call for more holistic, person-oriented research strategies (e.g., Bergman & Magnusson, 1997; von Eye & Bergman, 2003) that focus on the significance of single variables and of patterns in development, the developmental study of syndromes (typical patterns), and the detection of “white spots” in development in characterizing the individual as an “organized whole.”

This is not to say that each individual measure, even if a core indicator of the disorder or maladjustment, need be deviant or abnormal. Rather, a great deal of insight can be gained in finding patterns of normality and abnormality across measures as well as in creating broad behavioral and psychophysiological profiles. That is, disorder or risk may manifest in the dysregulation of responses across systems rather than alterations within an individual system (Bauer, Quas, & Boyce, 2002). An early example can be seen in Ax's (1970) work demonstrating that Schizophrenia is marked by poor coordination across systems (in this case, heart rate and respiration) rather than dysregulation within a single system.

It is in this endeavor that developmental psychopathology can benefit from its *developmental* roots. In the case of psychophysiological measures, their use in the study of psychopathology should not come with the expectation that the measure(s) will necessarily be patently deviant. There may be cases, such as institutionalization (Carlson & Earls, 1997), in which differences are apparent, but it is just as likely that a measure falls within the normal developmental distribution. The greatest information may be found when the measure is placed in the larger context of a physiological or behavioral profile.

For example, Raine (Raine, Venables, & Williams, 1990) collected heart rate, skin conductance, and EEG measures from a group of British adolescents ages 14 to 16. Ten years later, Raine and colleagues returned to see that 17 of the original 101 children now had criminal records. When comparing these two groups, Raine and colleagues found that the adolescents who went on to have a criminal record had lower

heart rates as well as dampened electrodermal and EEG arousal. Although the individual findings do not point to any gross deviance, disorder, or, to use a nineteenth-century term, degeneracy, they do point to an interconnected physiological system that may create a profile that is vulnerable to antisocial behavior.

Understanding Dissociations between Physiology and Behavior

It is of obvious interest to examine physiological change, concurrent with behavioral change, in response to a specific psychological challenge. Such associations provide another level of analysis around which one may interpret behavior, understanding the significance of the physiological change as it affects or supports a behavioral response. However, dissociations between overt behavior and physiology may also be of interest for understanding the individual's response to psychological challenge. In this instance, measurement of physiological change may provide important information that may not be readily apparent to the observer. An example of this may be found in the work of James Gross (Rottenberg, Kasch, Gross, & Gotlib, 2002) on emotion regulation. Gross and colleagues asked subjects who were watching videos designed to elicit different emotions to either freely respond or to inhibit their affective responses, measuring both overt behavior and autonomic responses. During the period in which subjects were inhibiting their affective responses, there was a noticeable decrease in observable behavior. However, these same subjects displayed a significant increase in autonomic activity (e.g., heart rate, blood pressure). This dissociation between behavior and psychophysiology was linked to more extreme concurrent depression and a decreased likelihood for satisfactory recovery. Dissociations between overt behavior and physiology may provide important information about psychological processes, in this case, inhibition of emotional behavior.

The issue of dissociation between physiology and behavior is complex, however. In the case of Gross's studies, subjects were given specific instructions and acknowledged complying with such instructions via self-report. However, in the absence of such task specificity and instruction, it is often difficult to interpret physiological change without a concurrent behavioral response. This dilemma underlies the first of two cardinal rules regarding psychophysiological research: Whenever possible, physiological responses should be anchored to behavior. Practically, this means that one should usually not interpret physiological change in the absence of concurrent behavioral change. There are, however, multiple exceptions to this rule. First, as described

earlier, if subjects are asked to inhibit behavior, then their physiological response becomes of interest independent of behavioral response. Second, tasks assessing sensory processing may not require a behavioral response. For example, examining brain stem auditory evoked responses or even mismatch negativity (i.e., an early ERP component that reflects a discrepancy between a stimulus and the traces in short-term memory produced by the immediately preceding stimulus) to auditory tones does not require active response from the subject. In these instances, it is not necessary to link behavioral response to physiology. It is in cases of complex cognitive or affective challenges that the interpretation of a physiological response without a behavioral anchor is problematic. Due to the complexity of the systems involved and the multidetermined processes influencing these responses, it is often difficult in such instances to specify the source of the physiological change and its contribution to a discrete psychological state.

Providing Insight into the Behavior of Preverbal and Young Children

An additional strength of the psychophysiological approach lies in its ability to provide insight into the behavior of preverbal infants and young children who cannot self-report or participate in interviews. In such cases, the psychophysiological approach provides a window onto reactivity and processing of stimuli that, together with behavioral analysis, offer a reasonable basis for judging an infant's or young child's response to psychological challenge. This is of particular importance when examining developmental psychopathology because researchers are often faced with the task of distinguishing between overlapping and nondistinct symptomatology due to children's limited behavioral repertoires.

The utility of these methods with infant and young child populations comes with several important caveats. It should come as little surprise that accompanying physical and psychological development is the development and change in underlying physiological systems, which support both of these areas. In some instances, the maturation of the system is rapid, over the 1st year of life, whereas for other systems there is consistent change through adolescence. For example, autonomic control systems change rapidly over the 1st year, and although mean heart rate levels change with development, the physiological system of vagal and sympathetic innervations, the links to respiratory control and blood pressure exist at birth and are stably in place by the end of the 1st year of life. On the other hand, concomitant with maturation of brain regions, particularly in corti-

cal areas, there are significant changes in frequency and amplitude of the EEG through adolescence. There are also major changes in the morphology of the components that are evoked by exogenous stimuli and that form the ERP. These changes in the physiology of the system directly affect the measurement of the system.

QUESTIONS ADDRESSED BY THE PSYCHOPHYSIOLOGICAL APPROACH

There are three broad areas in which psychophysiological methods are meaningfully applied: (1) examination of basic cognitive processes, (2) measurement of variations in physiological arousal and reactivity, and (3) examination of the processes surrounding motivation and emotion. In each of these areas, psychophysiology has a long history of research with both "normal" and clinical populations. In general, certain methods are more applicable for specific areas as opposed to others. Thus, for example, when examining basic cognitive processes such as attention, sensory processing, perceptual sensitivity, or memory, most of the work has entailed the use of ERP methods. Such methods require precision in stimulus definition and the timing of stimulus presentation and provide information about the timing and intensity of neural events involved in different aspects of cognitive processing. For studies in the preparedness of the system to react or respond to psychological challenge (e.g., arousal and reactivity), measures of the autonomic nervous system have been most commonly used. Assessments of arousal have traditionally been accomplished via measurement of sympathetic and parasympathetic activity. Such studies may examine heart rate, skin conductance, or sympathetic activity during a resting or baseline state and then during subsequent challenge and recovery to baseline. The use of psychophysiological methods to study emotion and motivation covers a wide range of methods, including those examining specific neural systems (e.g., the "fear" system) and those examining broad motivational processes (e.g., approach versus withdrawal). Included as well in this area is the work on the stress response and the physiological system involved.

The wide array of methods in part reflects the history of behavioral research in emotion, where precision in both the stimulus characteristics eliciting emotion and the approach to quantifying or identifying the presence of emotion have undergone important advances in only the past 30 years. This range of approaches has led to a range of studies, only some of which specify the nature of the stimulus and context in which it is presented. As well, among studies of

emotion or motivation only some anchor the physiological response to behavior, making interpretation of the physiological change ambiguous.

The following sections of this chapter are divided along these three broad domains. We first cover those methods useful for examining cognitive processes such as attention and review the empirical findings that are relevant for understanding both normative and clinical patterns of behavior in development. We then provide an overview of the methods used to examine the physiological organization of arousal and reactivity. The third section provides a review of those methods that may be useful for examining motivation, emotion, and emotion regulation in children. The literature discussed in each of the three broad domains illustrates how the application of psychophysiological methods has contributed to our current understandings of individual differences in developmental trajectories generally and developmental psychopathology in particular.

PHYSIOLOGICAL MEASURES OF COGNITIVE PROCESSING

In the psychophysiological literature there is often the implicit assumption of a dichotomy between cognition and emotion such that central nervous system measures are appropriate for the study of cognition and peripheral nervous system measures are suitable for studies of emotion (Keller, Hicks, & Miller, 2000). However, over the past 2 decades there has been a growing understanding of the interconnections between cognition and emotion in shaping both normative and disordered functioning and development. For example, recent research has suggested that individual biases to process or attend to negative threat information may play an important role in the development and maintenance of anxiety disorders in both children and adults (E. Fox, Russo, Bowles, & Dutton, 2001). In psychophysiology research, much of the work examining the relationship between cognition and emotion has relied on the ERP as a central methodological tool. This is due to the fact that these measures are very well suited to address questions of speed and efficiency of processing as well as perceptual sensitivity to variations in stimulus complexity. In addition, prepulse inhibition has been used to tap into basic cognitive processes and is therefore also explored in this section.

Event-Related Potentials

ERPs are currently the best noninvasive method for measuring the physiological manifestations of psychological processes within a small temporal window (Deldin,

Shestuyuk, & Chiu, 2003; Fabiani, Gratton, & Coles, 2000). ERPs are able to supplement the broad neuropsychological and neuroanatomical correlates of psychopathology assessed through the use of EEG, positron emission tomography (PET), and magnetic resonance imaging (MRI) by providing a more direct link between physiology and discrete instances of information processing.

There are four basic questions that can be asked with ERP data (Rugg & Coles, 1995). First, do the waveforms differ across experimental groups as a function of stimuli characteristics? Second, when do these differences appear? This question can be answered by looking at the timing of the divergence point. Presumably, divergences in the waveform indicate when processing begins to differ across stimuli or conditions. Third, are the processes underlying performance evoked to a different degree? This question is answered by measuring any differences in amplitude across the waveform. Fourth, do the ERPs fit any standard pattern? Psychophysiologicalists look for standard components, and deviations from the standard waveform are often taken as signs of deviance, delay, or immaturity. For example, individuals normally produce a smaller P50 ERP component to the second of a pair of identical stimuli. Schizophrenic individuals do not show a reduced P50 to the second stimulus, suggesting poor sensory filtering (Light & Braff, 1998; D. A. Smith, Boutros, & Schwarzkopf, 1994). These data suggest that poor sensory gating may lead to the perceptual and attentional deficits seen in Schizophrenia by allowing irrelevant or distracting information to interfere with normal functioning (Braff & Geyer, 1990).

Aside from marking the general processing of a particular stimulus, ERPs are also sensitive to the particular meaning the stimulus holds for the individual. For example, given a presentation of positive, negative, and emotionally neutral stimuli, researchers can use the neutral stimuli as a baseline against which to compare the processing of the affectively charged stimuli. One could then see if an individual's phenotypic presentation of, for example, depression is linked to an overresponse to the presentation of negative stimuli or an underresponse when presented with positive stimuli. The temporal resolution of the ERP also makes it a useful tool in the study of psychopathology because the core phenomena of emotion and attention are brief and require fast resolution to accurately reflect timing and intensity (Davidson, 1994). It is this sensitivity that makes ERP-based research attractive to researchers interested in the psychological, as well as biological, components of psychopathology.

Methodology for Event-Related Potentials

ERPs are time-locked electrophysiological recordings timed to the presentation of a specific stimulus or class of

stimuli (Coles & Rugg, 1995). The ERP for a particular condition or subset of the data is calculated by averaging over the EEG signals collected for each individual trial. The waveform produced is characterized by the size (amplitude) and timing (latency) of deflections in the wave. Increases in component amplitude and/or decreases in latency are taken as evidence that individuals are investing greater cognitive resources in processing the stimuli presented to them. Specific deflections or components are designated by their polarity (P = Positive; N = Negative) and either their order of appearance (e.g., N1, P1, N2) or their specific latency (e.g., N170, P360). For example, the P300 is a positive wave that occurs approximately 300 to 600 msec after stimulus onset and is maximal over central-parietal sites. The amplitude of the P300 is thought to vary with the task relevance and probability of a stimulus (R. Johnson, 1993) and marks the evaluation of stimulus significance. A detailed discussion of the methodology underlying ERP research can be found in Picton et al. (2000) and M. J. Taylor and Baldeweg (2002).

Although derived from a common electrocortical substrate, EEG and ERP measures appear to comment on different aspects of a particular behavior or process. For example, in their study of verbal and spatial working memory in adults, Gevins, Smith, McEvoy, and Yu (1997) found that changes in EEG were more likely tied to changes in the functional networks underlying task performance, whereas their ERP data were indexing the specific "operations being performed on internal representations" (p. 383). Along the same lines, Sobotka, Davidson, and Senulis (1992) found that EEG measures were more sensitive to incentive variations than were ERP measures.

There are a number of developmental changes that occur in the ERP through infancy and childhood (Cheour, Leppänen, & Kraus, 2000). First, the waveform becomes more complex and new components appear. For example, the Nc (negative component) generated by infants to stimuli will differentiate over time into an adult component (Richards, 2003). Second, ERP amplitudes appear to follow an inverted U shape as a function of age, perhaps reflecting greater processing demands and inefficiency during task performance (Ridderinkhof & van der Stelt, 2000). Third, ERP latencies grow progressively shorter, indicating an increase in processing speed (Thomas & Crow, 1994), perhaps due to more extensive myelination. Fourth, there are on occasion indications of a polarity shift in components over time (Novak, Ritter, Vaughan, & Wiznitzer, 1990). Finally, the localization of the component generator becomes more differentiated (M. J. Taylor & Baldeweg, 2002).

By far the most common use of the ERP has been to examine the physiological correlates of attentional processes.

This is true for both children and adults in healthy and clinical populations. Hillyard and Hansen (1986, p. 227) have suggested that the term attention "has become more of a chapter-heading word, encompassing a diverse set of processes and paradigms, than a precisely defined theoretical construct," but one cannot deny the central role attentional processes play in development. From birth, adaptive functioning is often dependent on the individual's ability to appropriately select those aspects of the environment that are of interest from among the constant and simultaneous presentation of competing stimuli. Ridderinkhof and van der Stelt (2000) argue that age-related improvements in this ability, particularly when under strong voluntary control, are one of the most profound advances in information processing that takes place in childhood. The advantage of the ERP paradigm is that it often forces the researcher to break down the larger construct of attention into its constituent parts in order to collect quantifiable data.

Traditionally, performance in attentional selection tasks is monitored via the speed and/or accuracy of an overt behavior in response to the information (e.g., stimulus identity or location) presented. For example, reaction times in response to cued and noncued visual targets have been compared as an indicator of the individual's ability to disengage and reorient attention (Posner & Cohen, 1984). As the various components in the standard ERP wave are thought to reflect different stages of processing, these data may help verify the mechanisms that shape overt behavior.

There are a number of standard paradigms in use for studying attention in both children and adults. Ridderinkhof and van der Stelt (2000) provide a very extensive review of attentional studies in developmental psychophysiology. As a result, the following discussion highlights only three types of tasks used in the field and the findings generated so far. Each discussion briefly notes the normative data in adults and children and then turns to findings with clinical and at-risk groups.

The first set of tasks is commonly labeled interference tasks. In this paradigm, participants are asked to overtly respond to information presented in one stimulus domain. Researchers look to see if performance is either hindered or facilitated by information in a second stimulus domain. The classic example of an interference or conflict task can be found in the Stroop (1935) paradigm. The traditional Stroop task presents individuals with a series of words and asks them to name the color in which the word is written, while disregarding the actual meaning of the word. Individuals are faster to respond when presented with congruent stimuli (the word RED in red ink) than when the stimuli are incongruent (the word RED in blue ink).

The earliest ERP study of the traditional Stroop task (Duncan-Johnson & Kopell, 1981) found no consistent differences across conditions. The researchers concluded that Stroop interference was related to conflicts in response selection rather than in the stimulus evaluation processes. However, more recent studies have indicated that there are detectable differences in ERPs generated by the traditional (color-word) Stroop (Ilan & Polich, 1999; Liotti, Woldroff, Pérez, & Mayberg, 2000; Schack, Chen, Mescha, & Witte, 1999; West & Alain, 1999). Early in the ERP wave, studies have found a distinct N1-P2-N2 complex (e.g., West & Alain, 2000b). These components are thought to index early sensory processing and low-level attention allocation (Hillyard, Luck, & Mangun, 1994). Traditional Stroop studies for the most part have not detected differences at this early stage across their two conditions: congruent versus noncongruent color words (however, see Atkinson, Drysdale, & Fulham, 2002). Rather, these studies have focused on more endogenous components, the P3 and N4 (e.g., Ilan & Polich, 1999). The larger amplitudes noted in the incongruent condition are thought to reflect the stimulus evaluation time and attentional requirements needed to ultimately suppress the information carried in the incongruent trials (West & Alain, 2000a). This interpretation also carries over to the positive slow wave prominently seen in traditional ERP studies (West & Alain, 2000b).

In the emotional Stroop, emotion words are substituted for the color words used in the traditional task. A number of emotional Stroop studies (Pérez-Edgar, 2001; Pérez-Edgar & Fox, 2003) have found that the general morphology of early ERP components (P1-N1-P2-N2) is roughly similar to those found in the traditional Stroop studies (e.g., West & Alain, 2000b). However, the later components (P3 and N4) were either attenuated or nonexistent. Overall, they indicate that there may be early processing differences across words of varying emotional valence, in line with data from other non-Stroop studies of emotion words (Shalev & Algom, 2000). A late slow wave also appears to distinguish between word categories. In particular, words conveying negative emotions seem to require or attract greater processing resources, as indexed by larger amplitudes and shorter component latencies (Hillyard et al., 1994; Schack et al., 1999).

The second major design, deviance detection tasks, requires participants to attend to the presence of a specific stimulus (the target) during the presentation of both target and nontarget stimuli. The most common deviance detection task is the oddball task. Prototypically, participants are asked to respond as quickly as possible to the presentation of a target that is embedded in a sequence of rare tar-

gets and frequent nontargets (Ridderinkhof & van der Stelt, 2000). One can also present a passive oddball design, during which no overt response is given. In fact, researchers often present participants with a book to read or video to watch in order to guarantee that they do not pay attention to the stimuli. This variant is used to examine the individual's bias in orienting to deviance or novelty and is quite useful to developmental researchers as no overt instructions need be given or followed.

Among adults, target detection in oddball tasks has been associated with increased P300, an enhanced N2, and a slow wave. The N2 is thought to reflect stimulus comparisons necessary for discriminating between the target and nontarget stimuli (Oades, Dittmann-Balcar, & Zerbin, 1997), and the slow wave may be associated with further elaboration of the target stimulus (Sutton & Ruchkin, 1984). Among individuals with Posttraumatic Stress Disorder (PTSD), oddball paradigms often produce attenuated P300s (Charles et al., 1995; MacFarlane, Weber, & Clark, 1993) and a delayed N200. McFarlane et al. suggested that the delayed latencies for the N200 reflect more time spent in stimulus discrimination, which allowed for fewer resources in later processing, as seen in the P300.

Subtracting the ERPs generated by the standard stimuli from the ERPs for the deviant stimuli produces a difference wave with a negative component that is maximal in frontal-central electrode sites and often peaks 200 msec poststimulus (Näätänen, 1990). This component, the mismatch negativity (MMN), is thought to reflect the mismatch between the current stimulus and the traces in short-term memory produced by the immediately preceding stimulus (Näätänen, 1992; for a review, see Cheour et al., 2000).

The developmental literature indicates that the MMN response can be seen very early, even in newborns (Kurtzberg, Vaughan, Kreuzer, & Flieger, 1995), although there is some controversy over the stability of amplitude (Kurtzberg et al., 1995; van der Stelt, Gunning, Snel, & Kok, 1997) and latency (A. H. Lang et al., 1995; van der Stelt et al., 1997) over time. One of the main reasons for the lack of consistency is due to the large inter- and intrasubject variability in young children (Kurtzberg et al., 1995). Studies focusing on the P3 (M. J. Taylor & Eals, 1996), N2 (Oades et al., 1997), and slow wave (Wijker, 1991) also indicate that the stimulus evaluation processes necessary for the task are present even in young children and that over time children make quantitative improvements in the efficiency of processing (i.e., shorter latencies and smaller amplitudes).

Reduced MMN amplitudes have been detected in individuals with depression (Ogura et al., 1993) and Schizo-

phrenia (Catts et al., 1995; Javitt, Doneshka, Grochowski, & Ritter, 1995; Javitt, Grochowski, Shelley, & Ritter, 1998; O'Donnell et al., 1993). The degree of attenuation among schizophrenics was correlated with ratings of negative symptoms (such as social withdrawal) but not positive symptoms (e.g., hallucinations and delusions; Catts et al., 1995; Javitt, Shelley, & Ritter, 2000). In a study of social withdrawal in young children, Bar-Haim and colleagues (Bar-Haim, Marshall, Fox, Schorr, & Gordon-Salant, 2003) found that children who were withdrawn in a novel social situation had smaller MMN amplitudes and longer latencies than their more sociable counterparts. Combined with the adult clinical and personality findings, Bar-Haim et al. speculated that individuals with a tendency for social withdrawal may share a difficulty in the early stages of auditory processing, which in turn shapes their subjective perception of their environment. A similar mechanism of perceptual processing may be at play in Attention-Deficit/Hyperactivity Disorder (ADHD), which has also been linked to attenuated MMN amplitudes (Kemner et al., 1996).

In the third major set of tasks, attention is primed on a trial-by-trial basis by a cue stimulus that instructs the individual on the identity or location of the target stimulus to attend to. By varying the location or identity of the target and cue, the tasks require participants to repeatedly disengage, orient, and reengage attention. The assumption is that the presence of the cue will prime mechanisms of selective attention, ensuring that the target stimulus will receive preferential processing while the processing of alternative stimuli is suppressed (Posner & Cohen, 1984). Examples of these shifting tasks are often referred to as Posner cued-attention tasks, and they consistently produce a "validity effect" marked by faster reaction times when responding to stimuli that appear in a previously cued location (valid trials) versus stimuli that are not cued (invalid trials).

There are a growing number of studies using ERP measures to observe neural activity during the Posner cued-attention task and address the timing of attentional mechanisms triggered by the task. The data indicate that the presentation of the cue engages attention during early perceptual processing (Luck, Heinze, Mangun, & Hillyard, 1990). As such, early ERP components (e.g., P1 and N1) generated by stimuli preceded by valid cues have greater amplitudes than ERP components corresponding to stimuli that were invalidly cued. The findings are most pronounced for posterior electrode sites.

For example, Anllo-Vento (1991) presented 6- and 8-year-old children with a centrally located arrow cue. They found an enhanced negativity from 200 to 500 msec after

the presentation of the cue, which was maximal in the hemisphere contralateral to the cued visual field. This "early directing attention negativity" was thought to reflect the selective recruitment of processes associated with spatial attention orienting. The presentation of the target in the validly cued location produced enhanced N1 and P1 amplitudes, reflecting the modulation of sensory areas by attention. Similar results were found in a recent study of 7-year-old children using peripheral, and presumably more exogenous, visual cues (Pérez-Edgar & Fox, 2005). These data indicate that attentional priming mechanisms are largely in place in young children.

Event-Related Potentials in the Study of Developmental Psychopathology

As noted in the discussion of specific tasks, affective processes have increasingly been incorporated into ERP studies (e.g., Gunnar & Nelson, 1994), expanding our understanding of the neural processing of affective behavior. This in turn is shaping the way ERP studies are incorporated into studies of risk and psychopathology.

For example, recent work suggests that late components of the ERP may reflect the discrepant nature of stimuli undergoing cognitive or affective processing (Pauli et al., 1997). In particular, affective stimuli elicit larger P300s and late positive slow waves than neutral stimuli (Kostandov & Azumanov, 1977; Williamson, Harpur, & Hare, 1991). This effect is even more pronounced when the stimuli are tailored to individual subject concerns. For example, Pauli and colleagues found that panic patients showed larger P300s and positive slow waves to somatic words versus nonsomatic stimuli.

Similar effects have been found when generally content-neutral stimuli are given affective significance. For example, introverted subjects performing a lexical decision task (De Pascalis, Fiore, & Sparita, 1996), a stimulus detection task (De Pascalis, 1994), and a stimulus prediction task (Bartussek, Diedrich, Naumann, & Collet, 1993) did not differ from extraverted subjects when the task was affect-neutral. However, when the experimenter introduced competition, providing win/loss feedback after each trial or set of trials, differences emerged. More specifically, introverts showed larger peak amplitudes (particularly the N2, P3, and P6) to loss feedback and extraverts showed larger peak amplitudes to win feedback.

In the adult literature, ERPs have been used with greater frequency to explore the information-processing mechanisms thought to underlie various disorders. In the case of Major Depression, for example, ERPs have been used to study negative biases in attention and memory

(Deldin et al., 2003). Specifically, the data indicate that depressed individuals are more likely to attend to and later recall more negative information, relative to nondepressed controls (B. P. Bradley, Mogg, & Williams, 1995). This cognitive style has been implicated in both the etiology and the maintenance of depressive symptomatology (Williams, Watts, MacLeod, & Matthews, 1997). ERPs allow for an examination of the mechanisms that may fuel the observed biases. In one such study, Deveney and Deldin (2004) found that depressed individuals showed larger amplitudes in a late slow wave when presented with pictures of faces expressing negative emotions. The slow wave has been associated with either elaborative encoding or subsequent retrieval processes of memory (R. Johnson, 1995). In addition, Deveney and Deldin's findings were strongest in the left posterior region, an area associated with face processing in working memory. Taken together, the psychophysiological measure helps test and refine our understanding of previously collected behavioral data.

A representative example of recent work in the developmental psychopathology literature can be found in Pollak's work with maltreated children (Pollak, Cicchetti, Klorman, & Brumaghim, 1997; Pollak, Klorman, Thatcher, & Cicchetti, 2001). Maltreatment and abuse place children at an extremely high risk for psychopathology (Cicchetti & Toth, 1995), and one area of particular concern is emotional functioning. For example, maltreated children appear to have a bias toward negative emotions. In infancy they manifest negative emotional expressions earlier and more often than nonabused peers (Gaensbauer & Hiatt, 1984). Over time, they are primed to detect negative affect in the environment (Weiss, Dodge, Bates, & Pettit, 1992) and have difficulty interpreting and responding to potentially hostile gestures in others (Klimes-Dougan & Kistner, 1990). Maltreatment and abuse may selectively increase children's psychological sensibilities to specific emotional cues, such as an angry face (Pollak et al., 2001).

Pollak and colleagues (1997) found that the ERP responses of maltreated children when processing emotion faces were sensitive to the context and attentional demands of the task at hand. Children ages 7 to 11 were presented with photographs of a single individual posing with either a happy, angry, or neutral facial expression. In this study, maltreated children had smaller component amplitudes and slower reaction times than their nonmaltreated counterparts when responding to the emotion faces. When asked to specifically attend to the angry faces, the maltreated children showed an increase in amplitude over the happy face condition, whereas the other children showed an equivalent response. These data indicate that the emotion processing

need not be completely stimulus-driven, but may depend on the contextual importance of the stimulus and task at hand. Indeed, a follow-up study (Pollak et al., 2001) indicated that the effect was specific to angry faces, suggesting that maltreated children do not exhibit a global deficit in emotional information processing.

Future Directions in the Use of Event-Related Potentials

ERP measures have allowed researchers to examine the processing mechanisms that bridge the presentation of a stimulus with the observation of overt behavior. Indeed, the technology opens a window onto cognition even in the absence of behavior. In general, it appears that affective information can influence the topography of ERP components if the affective loading of the stimulus is high and the individual attends to stimulus meaning (Johnston & Wang, 1991; Williamson, Harpur, & Hare, 1991). The ERP has proven to be a robust, noninvasive measure amenable across a wide age range of uses, yet there are a number of considerations that should be kept in mind when collecting and interpreting such data.

First, a better understanding of the development of the ERP, independent of our interest in psychopathology, will be needed to make the best use of the methodology. One cannot presume that measures from children and adults are equivalent in structure or function. For example, many of the studies incorporating ERP measures into the study of emotion and emotional processing have used pictures of facial affect as the central stimulus (e.g., M. H. Johnson & Morton, 1991; Nelson, 1987; Pollak et al., 1997). These stimuli are relatively easy to produce, can be standardized and incorporated across a set of studies, and are in most cases appropriate for use across a wide developmental range. Indeed, ERP measures have been successfully used in studies with participants as young as 6 months (e.g., Nelson, 1994). Although the technology allows researchers to compare children and adults on identical measures generated via identical stimuli presented in the context of the same task, there are important developmental differences involving both the psychophysiological measures of interest themselves and the processing mechanisms they are thought to reflect.

The ERPs generated in children by the task at hand often do not correspond to those of adults. These age-related differences are more pronounced the younger the child. For example, as noted earlier, adults participating in an oddball paradigm display an enhanced N2 component to the presentation of the target stimulus approximately 200 msec after onset (Oades et al., 1997). Infants participating in similar procedures display a large nega-

tive component (morphologically similar to an adult slow wave) occurring approximately 400 to 800 msec after the stimulus. This component is known as the Nc because it is negative in polarity and maximal in central sites (Richards, 2003).

Even when dealing with older children, who often generate ERP waves that are morphologically comparable to those of adults, one cannot assume that visual similarity reflects an equal similarity in the psychological processes involved. This becomes evident when trying to compare the performance of children and adults across conditions of the same task. For example, Kestenbaum and Nelson (1992) presented 7-year-old children and adults with pictures of angry, happy, fearful, and surprised faces and asked them, across two conditions, to respond to either the happy or angry face. Adults in this study showed greater ERP (e.g., P300) amplitudes to the happy faces. The children, however, showed larger amplitudes for the angry faces. In addition, this finding held only when calculating the area scores for the component. When peak values were calculated there was no differentiation across valence. The method of analysis made no difference in the adult data.

Because ERPs are derived from raw EEG signals, the issues and concerns discussed in that section are also applicable here. For example, ERP component amplitude is sensitive to the overall power of the EEG signal. As a result, age-related changes in ERP amplitude to the presentation of a particular stimulus need not solely reflect developmental changes in the ability to process or derive meaning from that stimulus. Rather, it may be largely driven by maturational changes in the overall strength of the EEG signal. Group differences observed in the ERP may also similarly be rooted in variations in the underlying EEG substrate. For example, Lazzaro and colleagues (Lazzaro, Gordon, Whitmont, Meares, & Clarke, 2001) found that amplitude reductions in the P3 component of children with ADHD could be linked to prestimulus increases in theta wave activity.

As such, it is important that any age-related changes in the ERP can be traced to manipulations of the task or conditions at hand. If not, it is difficult to disentangle results from the general effects of brain maturation. For example, after reviewing a variety of deviance detection (oddball) studies focusing on the P300 and finding that age-related changes in topography were invariant across myriad stimulus and task demands, M. J. Taylor (1988) came to the somewhat controversial conclusion that the findings were due to the expression of brain maturation, not developmental changes in specific cognitive abilities.

Prepulse Inhibition

It has long been surmised that seemingly simple human reflexes do not function in isolation in the intact nervous system (Fearing, 1930). For instance, at the turn of the previous century, Bowditch and Warren (1890) documented that the human patellar (i.e., knee-jerk) reflex was substantially suppressed when subjects clinched their hands in response to a bell milliseconds before the knee was stimulated. Years later, Hilgard (1933) documented changes in the amplitude of the eyeblink (i.e., startle) reflex in response to the presentation of a loud, startle-evoking noise when a visual stimulus (i.e., flashing light) was presented prior to the auditory stimulus. Further, Hilgard found that temporal variation in the presentation of the visual stimuli served to differentially modify the acoustic startle response. These early studies mark the first evidence to suggest that reflexes, previously thought to be isolated functions of the central nervous system, are in fact modulated by psychophysiological processes (M. E. Dawson, Schell, & Böhmelt, 1999). Hence, measurement of the degree of modulation in the startle response permits exploration of psychological states on physiological responding.

Graham, Putnam, and Leavitt (1975) showed that the presentation of a nonstartling, neutral, "lead" probe (e.g., a series of tones) immediately prior to the startle probe yields an attenuation of the blink amplitude, a phenomenon referred to as prepulse inhibition, defined formally as "the normal suppression of the startle reflex when the intense startling stimulus is preceded 30 to 500 msec by a weak lead stimulus" (Swerdlow & Geyer, 1999, p. 115). The opposite pattern was documented for lead stimuli that were presented at longer (>1,400 msec) intervals, describing a phenomenon referred to as long-lead facilitation. Graham's findings regarding the inhibition or facilitation of startle relative to temporal variation in the presentation of lead stimuli has been well replicated and is a robust phenomenon in adults (Ornitz, 1999).

The neural circuitry involved in prepulse inhibition is regulated by forebrain and limbic structures that descend on the pallidum and pontine tegmentum. This top-down pathway is not direct and involves inputs to the striatum from the limbic cortex, striatal connections to the pallidum from the striatum, and inputs to the pontine tegmentum from the pallidum. Such top-down effects of higher-level processes on brain stem modulation of startle are related to early attention and sensory processing of input. The temporal variation in the presentation of the lead stimuli, relative to the experimental stimuli (i.e., affective; see discussion of affective modulation of startle later in chapter) and the

startle probe, has been investigated and findings here mark an important contribution to understanding the role of attention and affect in startle modulation. In their review of this literature, M. M. Bradley, Cuthbert, and Lang (1999, pp. 167–169) have summarized these findings into six general conclusions:

First, strong inhibitory effects are obtained when blink reflexes are elicited immediately after picture onset. Second, reflex inhibition is maximal 300 msec after picture onset, which is somewhat later than is typically found for simpler foreground stimuli. Third, at the point of maximum inhibition (300 msec), reflex inhibition is significantly larger for emotional pictures (pleasant or unpleasant), compared with neutral materials. Fourth, reflexes continued to be relatively inhibited, compared with responses elicited in the interpicture interval, for up to 3 s after picture presentation, at which time reflex magnitude appears to asymptote for all picture contents. . . . Fifth, by 500 msec after picture onset, reflexes are significantly augmented for unpleasant, compared with pleasant materials, suggesting that affective modulation has been initiated by this time. Affective modulation then continues throughout the picture-viewing interval. Sixth, no significant effects of affective valence are found for reflexes elicited after picture offset.

Bradley and her colleagues interpret such effects as the result of attentional mechanisms involved in the initial processing of the foreground stimulus. Essentially, the more interesting the prepulse stimulus is, the more resources are involved in the encoding of it. However, at the point at which encoding of the stimulus is complete (at approximately 500 msec), the affective quality of the stimulus has been perceived and the startle reflex will henceforth be modulated by the affective nature of that stimulus until the time when the stimulus is no longer presented.

According to Graham and colleagues (1975), prepulse inhibition is due to a “transient detecting reaction” that serves to suppress startle reactions temporarily to ensure that perceptual processing of the lead stimulus is complete. In this way, prepulse inhibition serves a protective function, inasmuch as attenuated startle reactions allow for increased allocation of cognitive resources to the stimulus encoding process. Thus, the individual differences in prepulse inhibition are of scientific interest in their own right, as variation in the degree to which the startle response of participants is modulated following the presentation of simple lead stimuli is thought to be an indicator of individual differences in attention and sensory processing as relevant to initial perceptual encoding of information at lower brain stem levels (Ornitz, Hanna, & Traversay, 1992).

Startle Methodology

The startle reflex is thought to be a primitive defensive response that may serve at least two purposes: (1) to avoid bodily injury, as in the function of the eyeblink; and (2) to halt ongoing activity and prepare the organism for fight or flight in the face of looming threat (P. J. Lang, 1995). Landis and Hunt (1939) were the first to provide a detailed depiction of the startle response in humans. These researchers used slow-motion video documentation to characterize the response that followed the presentation of a pistol shot. They reported that the startle response consists of a forward head thrust, descending flexor wave reaction, and the sudden closure of the eyes. It is the last of these responses that is used as the index of startle amplitude, as it has been shown to be the earliest, fastest, and most stable process involved in the startle response (P. J. Lang, Bradley, & Cuthbert, 1992). There is considerable variability in the degree of amplitude of the startle reflex related to attention and affective processes. This variability in amplitude is used as an index of an organism’s underlying emotional state. Researchers interested in the affective modulation of the startle reflex tend to rely also on additional psychophysiological indices of emotional reactivity and attention, including heart rate, blood pressure, skin conductance, ERPs, and facial electromyographic responses. These are also incorporated into the protocol to confirm that the appropriate/desired level of affective arousal has been achieved by the emotional stimulus (M. M. Bradley et al., 1999).

The eyeblink startle reflex is measured with electromyogram (EMG) by placing two electrodes under one eye. The EMG waveforms are rectified and integrated (see van Boxtel, Boelhouwer, & Bos, 1998, for a full review) and scored for degree of amplitude in the EMG response. Onset of the eyeblink reflex is triggered most often with the presentation of brief, high-intensity white noise for baseline startle and during the presentation of experimental stimuli. Experimental stimuli have ranged from visual stimuli such as pleasant or unpleasant pictures or videos (M. M. Bradley & Lang, 2000; Cuthbert, Bradley, & Lang, 1996; P. J. Lang, Bradley, & Cuthbert, 1990), administration of shocks (Hamm & Stark, 1993), use of air blasts administered to the neck (Grillon & Ameli, 1998), and manipulation of levels of light and darkness (Grillon, Morgan, Davis, & Southwick, 1998; Walker & Davis, 1997). According to Grillon and Baas (2003), the method used to assess the degree of change in startle amplitude between the control and experimental conditions has major implications for the results of a study and should be based on knowledge of the particular underlying system being as-

sessed. The startle paradigm is ideal for use with infants and young children as well as adults and the elderly. However, choice of emotional stimuli used for experimental conditions must be appropriate for the particular age group targeted in the study (Grillon & Baas, 2003).

Prepulse Inhibition and the Study of Developmental Psychopathology

The literature exploring the role of attention in the modulation of the startle reflex in infants and children provides preliminary evidence for a meaningful developmental trend in the degree to which variable lead intervals affect startle responses. In his review of this literature, Ornitz (1999) concludes that there is little evidence for the presence of prepulse inhibition prior to the age of 8 years. For instance, there is a 25% response inhibition in 2- to 6-month-olds, 23% inhibition in 3-year-olds, and 30% inhibition in 5-year-old boys (Ornitz, Guthrie, Kaplan, Lane, & Norman, 1986). After age 8, however, adult-like levels of prepulse inhibition are evident. This effect is consistent with the notion that prior to the middle of childhood, young children lack impressive degrees of inhibitory control. This notion regarding inhibitory control is further supported by data that have revealed peaks in the degree of long lead stimulus startle facilitation in 3-year-olds relative to adults and children older than 8 (Ornitz et al., 1986). Ornitz suggests that these findings provide preliminary evidence that the brain stem mechanisms that mediate startle response modulation are developing during childhood and are not fully mature until approximately age 8. Such a conclusion is indeed tentative at best, as no replication of Ornitz's developmental findings yet exists. The notion that these patterns of findings are due to the increase in the development of inhibitory control across the preoperational to concrete operational years is certainly plausible. One important contribution to this area will be the examination of attentional modulation of startle in children between ages 3 and 8, during the transition from preschool to middle childhood.

To date, there are only a few published studies that have examined the role of startle modulation in childhood psychopathology. Two are investigations of attentional modulation of startle undertaken by Ornitz and his colleagues. In the earliest of these works, Ornitz and Pynoos (1989) examined startle modulation based on variable lead intervals, on the premise that the exaggerated startle pattern manifested by individuals with PTSD would yield atypical patterns in attentional modulation of startle assessed in the laboratory. They anticipated that children with PTSD would show a reduction in prepulse inhibition and enhanced startle facilitation due to longer lead inter-

vals. Ornitz and Pynoos assessed their small sample of children with PTSD and a normative sample of nonmatched controls multiple times across 2 years (six of the children in the study had onset of PTSD following a sniper attack at their school playground and a seventh child in the study witnessed the murder of his father). The children with PTSD showed less startle inhibition with prestimulation relative to controls. Close examination of the case that witnessed murder revealed that the reduced prepulse inhibition was quite variable across the 2 years following the incident, with the most pronounced effects emerging at assessments closest temporally to the traumatic event. The authors concluded that the lack of prepulse inhibition of the PTSD group relative to normal controls might indicate a slowing in the normal development of the brain stem mediated function due to severe stress. Additionally, although marked by many limitations, including the lack of a matched control sample and a small sample size, this study provides preliminary evidence to suggest that the deviant startle pattern in children with PTSD is most pronounced at temporal points closest to the traumatic incident and may ameliorate over time.

In another study of childhood psychopathology and startle modulation, Ornitz and his group (Ornitz et al., 1992) examined differences in prepulse inhibition and long-lead facilitation of startle in boys ages 6 to 11 diagnosed with ADHD, primary nocturnal enuresis, and the comorbid condition (i.e., both ADHD and enuresis) relative to normal peers. In their clinical sample, a high degree of comorbidity between nocturnal enuresis and ADHD was found (with enuresis occurring in some 30% of boys with ADHD). Hence, Ornitz and his colleagues explored the extent to which previously documented (Anthony, 1990) startle abnormalities in children with ADHD are more closely related to the attention deficit primary to their condition or to the physiological immaturity associated with nocturnal enuresis. The findings of this study are indeed quite telling, for although no ADHD effects were noted, all enuretic boys (i.e., children with both primary and secondary nocturnal enuresis) showed immature patterns of prepulse inhibition and long-lead facilitation that were comparable to levels found in 5-year-old children. The authors interpreted these findings as providing evidence for underdeveloped mesopontine reticular mechanisms, which serve to mitigate the lower-level processing of the signals associated with urinary continence. During sleep, appropriate functioning of the inhibitory functions involved in urinary continence are dependent on the modulation of sensory input to indicate bladder fullness by the spinal reflex activity of the

pontine micturition center. This pathway may be anatomically and functionally related to the pathways involved in startle modulation, inasmuch as the processing of sensory information relevant to startle is modulated by an inhibitory pathway that parallels the inhibitory pathway in the mesopontine lateral tegmental area associated with the processing of sensory signals from the bladder. Hence, “primary nocturnal enuresis can be considered a disorder of early sensory processing, that is, a dysfunction of subcortical preattentive mechanisms” (p. 447).

Such a finding marks an important contribution to current understandings of developmental psychophysiology on several grounds. First, a good deal of research has sought to understand the neurophysiological nature of nocturnal enuresis with little resolution. For instance, as Ornitz and his colleagues indicate, deviant sleep patterns, arousal mechanisms, and bladder functions have been implicated as the source of nocturnal enuresis, and each of these literatures has been met with mixed results. The findings involving startle modulation offer new and exciting directions for understanding the nature of primary nocturnal enuresis as a deficit in early sensory processing. The lack of effect for the boys with ADHD suggests that ADHD is perhaps less related to lower-level preattentive mechanisms than it is to higher-level processing, such as executive functions located in the prefrontal cortex.

Future Directions in the Use of Prepulse Inhibition

The use of the startle methodology to the field of developmental psychopathology, although still very much in its infancy, holds promise. Studies of the temporal variation of lead intervals provide windows onto the role of the most basic processes, including that of early preattentive sensory processing, on pathological development. Ornitz’s work (Ornitz et al., 1992; Ornitz & Pynoos, 1989) has demonstrated that central nervous system immaturity associated with basic processing is associated with childhood-onset PTSD and primary nocturnal enuresis, and not ADHD. Indeed, issues of sensory gating are relevant to many psychopathological conditions, particularly Schizophrenia and conditions of anxiety, learning disabilities, mental retardation, and Pervasive Developmental Disorders. It is especially important to note that the prepulse inhibition paradigm is ideal for use with such compromised populations, as the laboratory paradigm places no burden on the participant to read or socially interact with an experimenter. As such, the prepulse inhibition methodology can meaningfully be applied to special populations of children, and its use should yield great strides in uncovering

the aberrant sensory processing associated with a diversity of psychopathological conditions.

MEASURES OF PHYSIOLOGICAL AROUSAL

Although variations in psychopathology differ in etiology, developmental course, disruptiveness, and amenability to treatment, they are thought to share some core characteristics. Chief among these is the notion that children diagnosed with or at risk for psychopathology have a difficult time adjusting and adapting to the shifting demands of their environment. A good deal of work in developmental psychopathology has focused on individual differences in the preparedness of the system to react or respond to psychological challenge. Related to this are differences in level of reactivity to threatening stimuli and in the subsequent regulation of fight/flight responses. Measures covered in this section include measures of autonomic arousal, including heart rate, pre-ejection period, electrodermal activity, and vagal tone, as well as additional measures of physiological arousal, namely, cortisol and EEG power.

Walter Cannon (1915) offered the earliest account of the functional significance of the autonomic nervous system (ANS). According to Cannon, the ANS served to keep the organism in a state of homeostasis, with two separate branches of the ANS (sympathetic and parasympathetic) serving in reciprocal harmony. The ANS is of interest to psychopathological processes because it plays a central role in mitigating somatic responses that are associated with perceived environmental threat (Boyce et al., 2001).

In a classic paper on the relationship between somatic and psychological processes, Cannon (1928) reported associations between negative affect and heart rate, hypertension, the digestive system, the menstrual cycle, thyroid function, and the immune system. ANS reactivity has been found to correlate with behavioral inhibition in infants and young children (N. A. Fox, 1989), internalizing and externalizing psychopathology in middle childhood (Raine, 2002), and ADHD and Conduct Disorder in adolescents (Beauchaine, Katkin, Strassburg, & Snarr, 2001).

This portion of the chapter first discusses the measurement of sympathetic activation and includes discussion of measures of heart rate via electrocardiogram (ECG), pre-ejection period, and electrodermal activity. Measurement of the activation of the parasympathetic branch of the ANS is discussed next, followed by a review of the findings regarding autonomic reactivity and the development of psychopathology.

Measures of Sympathetic Activity and Reactivity

The sympathetic branch of the ANS prepares the body for the release of energy and is activated during fear-eliciting situations. Activation of this branch yields an increase in blood circulation to the muscles vis-à-vis increases in heart rate and force of heartbeats (Ohman, Hamm, & Hugdahl, 2000). Sweat glands also respond during activation of the sympathetic branch, such that increases in perceived threat result in filling of eccrine sweat glands. Psychologically, sympathetic autonomic reactivity is of interest to psychophysiologicals because of its relationship to the activation of the approach-withdrawal system, the motivational system implicated in individual differences in arousal (Fowles, 1980).

Heart Rate

According to Fowles (1980), heart rate is a sympathetic manifestation of Gray's (1975) behavioral activation system (BAS). In his landmark theoretical paper, Fowles points to the abundant body of early empirical evidence that found associations between heart rate acceleration and behavioral activation when level of somatic activity is controlled (e.g., Belanger & Feldman, 1962; Ehrlich & Malmö, 1967). According to Gray, the BAS also mitigates behavioral response patterns of active avoidance. Fowles cites additional work, such as that of Obrist (1976, as cited by Fowles, 1980), that found heart rate accelerations during conditions in which participants were able to actively avoid shocks based on successful task performance. In Fowles' own words, "The BAS represents a central control system which responds to incentives and whose activity is reflected in increased HR [heart rate]" (p. 92). It is important to note, however, that simple estimates of heart rate are by no means uncontaminated estimates of sympathetic functioning, as patterns of heart rate acceleration and deceleration are associated with both somatic activity (Fowles, 1980) and respiration (Porges, McCabe, & Yongue, 1982). Hence, heart rate is an index of activation of the BAS (either in the form of reward seeking or active avoidance of punishment) when degree of somatic activity and respiration are controlled.

ECG is a psychophysiological measure that involves recording the electrical potentials of the heart during each cardiac cycle (Papillo & Shapiro, 1990). Heart rate is perhaps the most salient and easily observable manifestation of sympathetic ANS arousal. The large bioelectrical signals generated by the heart are recorded from placement of electrodes on the body's surface. Although as many as 12 leads can be tactically placed on the limbs and chest to di-

agnose irregularities of the heart, psychophysiologicals are typically interested in heart rate alone, which can be reliably recorded from as few as two electrode sites. Positioning of the ECG electrodes is not a critical consideration in ECG setup, as the large electrical signals can be recorded from almost any site in the general region of the heart. Although it is not within the scope of this chapter to provide a depth of knowledge about ECG indices (see Papillo & Shapiro, 1990), guidelines for those interested in psychophysiological research can be found in Jennings (1981).

There are two indices determined by ECG that warrant mention. The first is simple heart rate, which is determined by the number of beats per some prespecified unit of time, typically 1 minute. Heart period, or the interbeat interval, is the elapsed time between two successive heart cycles and is usually determined online by a computer. The decision of which index is most appropriate depends on a number of considerations, including whether the research questions involve analysis of individual or group differences, if the participants are infants or adults, and whether raw scores or change scores are desired (Graham, 1978; Graham & Jackson, 1970; Jennings, Stringfellow, & Graham, 1974).

Systolic Time Intervals

More recent work in autonomic reactivity has relied on the use of measurement of the systolic time interval as an estimate of autonomic reactivity. Measurement of the pre-ejection period (PEP) is one such estimate and is defined operationally as the temporal latency between the onset of isovolumetric contraction (i.e., ventricular depolarization) and the onset of left ventricular ejection (Sherwood, 1993; Uchino, Cacioppo, Malarkey, & Glaser, 1995). The PEP is obtained by collecting both ECG and an impedance signal of thoracic blood flow, such that PEP equals the temporal interval from the Q wave on ECG to the B point on the dZ/dt signal. Shorter intervals indicate greater sympathetic activation. The PEP of the cardiac cycle is a sensitive measure of sympathetic tone that is free of parasympathetic influence inasmuch as the ventricular myocardium is innervated almost exclusively by the sympathetic nervous system (Cacioppo, Uchino, & Bernston, 1994).

Electrodermal Activity

Another method for gauging activation of the sympathetic ANS involves the measurement of electrodermal activity (EDA). Before the turn of the previous century, Vigouroux (1879, as cited by M. E. Dawson, Schell, & Fillion, 2000) began using degree of tonic skin resistance as a clinical diagnostic tool. Fere (1888, as cited by M. E. Dawson et al.,

2000), extending Vigouroux's work, revealed that skin resistance could be measured by passing a small electrical current between two electrodes placed on the skin. Contemporary psychophysiological researchers are still quite interested in the degree of skin resistance—often conceptualized as its opposite, skin conductance—that is elicited following the passage of an electrical current between two electrodes placed on the skin.

EDA is the result of activity of eccrine sweat glands found on the surface of the body and largely concentrated in the hands and feet. The eccrine glands are responsible for regulation of skin temperature, although the glands located on the hands and feet are also thought to play a role in grasping and are more reactive to emotional versus thermal stimuli than are eccrine glands located on other skin surfaces. The relationship between sweat gland and electrical activity is such that, as the sympathetic ANS is activated, sweat fills sweat ducts on the surface of the skin and electrical conduction is increased (M. E. Dawson et al., 2000). Eccrine sweat gland activity is controlled by cholinergic innervation from fibers that originate in the sympathetic system. Hence, unlike cardiac functioning, EDA receives no parasympathetic input (Fowles, 1980).

Functionally, EDA is thought to reflect activation of the behavioral inhibition system (BIS; Fowles, 1980; Gray, 1975). In his synthesis of the EDA literature, Fowles called on studies such as Elliott's (1969) study of autonomic arousal and Stroop performance and Haywood's (1963) work in autonomic reactivity and delay of auditory feedback to illustrate the utility of EDA as a measure of the BIS, as these studies revealed that autonomic reactivity was manifest by EDA (but not heart rate) during conditions of nonreward. Fowles cautions, however, that EDA's index of activation of the BIS is confounded by degree of cognitive activity (e.g., orienting, itself mediated by the BIS) involved in the laboratory paradigm (Szpiler & Epstein, 1976), frequency of response required by a task (with frequent responding yielding nonspecific EDA patterns; Schneider & Fowles, 1978), and degree of hydration of the skin (Bundy & Mangan, 1979). However, with careful experimental control, Fowles has suggested that EDA can be used to assess degree of emotional arousal stemming from activation of the BIS.

Measures of Parasympathetic Activity and Reactivity

The parasympathetic branch of the ANS serves a catabolic, energy-restoring function (Ohman et al., 2000). Activities supported by the parasympathetic branch include gastric

and intestinal motility, secretion of digestive juices, salivation, and increased blood flow to the gastrointestinal tract. Cells of the parasympathetic branch are located in the nuclei of the cranial nerves (3, 7, 9, and 10) and in the sacral region of the spinal cord. Focus on this division of the ANS has been centered on the role of the vagus, the cranial nerve that regulates deceleratory parasympathetic activity (Beauchaine, 2001) and hence mediates patterns of cardiac reactivity during periods of orienting and fight/flight responding. Historically, interest in the parasympathetic branch of the ANS was based on the notion that it worked with the sympathetic branch in a symbiotic fashion such that each were separate, antagonistically related components of one unitary system. However, evidence offered by Porges (1995) indicates that the parasympathetic system is more complex than previously thought.

Heart Rate Variability (*Vagal Tone*)

Quantification of heart rate variability is used as an index of parasympathetic functioning, or vagal tone. The vagus itself contains both afferent and efferent fibers that play a role in cardiac functioning. Efferent vagal fibers from the brain stem extend to the sinoatrial (SA) node. Activation of these inhibitory fibers yields a decrease in SA firing, which yields a general attenuation in heart rate. Afferent fibers, originating in the heart, extend to the nucleus tractus solitarius and provide feedback to the brain that ultimately serves to regulate generalized cardiac functioning. Vagal tone, or RSA, is the result of vagal efference occurring during exhalation (slowing the heart) and of vagal efference during inhalation (increasing heart rate). Because the sympathetic regulation of the heart via acceleratory sympathetic projections to the SA node confound simple estimates of heart rate, neither heart rate nor heart period alone can serve as an uncontaminated index of RSA.

The simplest methods for gauging RSA rely on the range, variance, or standard deviation of the cardiac interbeat interval. The peak-to-trough method proposed by Fouad, Tarazi, Ferrario, Fighaly, and Alicandri (1984) involves the monitoring of both interbeat interval and respiration and is the mathematical difference between the longest interbeat interval corresponding to expiration and the shortest interbeat interval corresponding to inspiration. Porges (1986) recommended using spectral analysis to isolate the portion of variance within the interbeat interval that is due to RSA from that which is due to heart rate.

The functional significance of the RSA is provided by Porges's (1995) polyvagal theory. Porges argued that the vagal system is controlled by two very distinct motor systems, each of which has different evolutionary origins and

locations. One system originates in the dorsal motor nucleus, is phylogenetically older, and is termed the *vegetative vagus*. This system is associated with reflexive regulation of primitive functions, including the deceleration of heart rate during states of attentiveness and primitive behavioral freezing in the face of perceived threat. The other motor system is purely mammalian, originates in the nucleus ambiguus, and is called the *smart vagus* because it is associated with attention and orienting responses. In the face of impending threat, higher-order mammals must first orient and then either become engaged or enter into a fight-or-flight behavioral pattern. Engagement is associated with vagal withdrawal, and the emotional reaction triggered by a fight/flight response system is associated with a nearly complete vagal suppression, or “vagal break,” which is accompanied by sympathetic heart rate acceleration. As such, cardiac reactivity postorientation, during engagement of the fight/flight system, is mediated by the activation of the smart vagus. The vegetative vagus, in contrast, mediates heart rate deceleration during orienting behavior (Porges, 1995).

As Beauchaine cautions (2001), the functional significance of RSA is by no means clear-cut and is largely dependent on the context in which RSA data are collected. According to his review, RSA reflects generalized temperamental reactivity and emotionality when it is obtained during quiescent states, such that high-RSA infants are more likely to be extremely emotionally reactive (i.e., either affectively negative or positive in response) than infants who have lower levels of RSA (N. A. Fox, 1989; Stifter & Fox, 1990; Stifter, Fox, & Porges, 1986). In contrast, when RSA is obtained during specific environmental demands, the measure will reflect the manifestation of either attentional focus *or* emotion regulation. For example, in a sample of boys ages 5 to 9 years, Weber, van der Molen, and Molenaar (1994) found that RSA decreased significantly from baseline during an attention-demanding task. Indeed, Beauchaine argues that there is ample consistency in the infant, childhood, and adult literature to conclude that periods of cognitive engagement result in partial vagal withdrawal.

The literature exploring emotional reactivity to specific emotionally charged events is less clear. Calkins and Fox (1997) reported RSA reduction from baseline in preschoolers during the presentation of *both* affectively positive and negative events. Beauchaine (2001) suggests that although moderate degrees of vagal withdrawal are associated with adaptive responses to danger, excessive vagal withdrawal is associated with emotional lability, or dysregulation, and is therefore an important index of psychopathology, particu-

larly when parasympathetic reactivity is supplemented with measures of sympathetic reactivity such as EDA and heart rate, which can then serve to help specify whether or not activation involves Gray's (1975) BAS or BIS.

Autonomic Reactivity and Developmental Psychopathology

Most substantive work in the area of autonomic reactivity and childhood psychopathology has emphasized the role of the BIS, BAS, and, more recently, the parasympathetic regulatory system in the childhood onset of aggression and impulsivity (Beauchaine et al., 2001; Boyce et al., 2001; Harden & Pihl, 1995; Herpertz et al., 2003; Raine, 2002). For instance, the application of both sympathetic and parasympathetic measures of reactivity to childhood externalizing disorders has yielded great strides in the disentanglement of the distinctive etiological underpinnings of ADHD and Conduct Disorder (Beauchaine et al., 2001). More general studies of childhood psychopathology have revealed distinctive patterns of autonomic reactivity associated with internalizing versus externalizing conditions.

Boyce and his colleagues (2001) conducted a cross-sectional investigation of autonomic reactivity, including measures of sympathetic and parasympathetic responding and psychopathology, in a sample of 6- and 7-year-olds. Included in their reactivity protocol were indices of heart rate, RSA, and PEP. Autonomic reactivity measures were obtained at baseline and across various challenging contexts, including a structured interview, a digit span task, placement of lemon juice on the tongue, and during the showing of two emotion videos designed to evoke fear and sadness. Children were divided into four symptom groups: children with low symptoms on both internalizing and externalizing, high internalizing children, high externalizing children, and children who scored high on both externalizing and internalizing disorders.

Results revealed that children who scored high on internalizing problems showed significantly more parasympathetic reactivity (low RSA). Children who scored high on externalizing manifested lower degrees of parasympathetic and sympathetic reactivity than children in the low symptom group. Subsequent analyses examining the discriminant validity of the autonomic profiles of the sample revealed that children with high internalizing problems could be significantly discriminated from children in the low symptoms group based on a profile of high parasympathetic reactivity during challenge tasks and recovery from those tasks. Externalizing children, in contrast, were significantly discriminated from the other three groups based on a profile that reflected a generalized (i.e., non-task-specific) pattern of

low sympathetic and parasympathetic reactivity. Children in the high internalizing/externalizing group showed lower generalized sympathetic reactivity only. Child gender and patterns of autonomic reactivity were also explored in this study, and no evidence of main or moderating effects were found. Hence, results of this study are indicative of differential degrees of reactivity that are specific to each of the broadband classifications of childhood pathology. High internalizers in Boyce's study showed dysregulation in fight/flight responding during and after challenging paradigms, providing evidence that the underlying substrate of childhood anxiety and depression is related to the perception of environmental threat. In contrast are externalizers, who manifest a generalized pattern of autonomic underarousal that does not seem to be linked to any specific event. Such children manifested global dysregulation in the fight/flight system and abnormal levels of reactivity related to BAS functioning.

In a similar study, Harden and Pihl (1995) found that boys who were classified as high on internalizing and externalizing behavior problems evidenced an ANS profile of hyperreactivity when compared to children with no behavior problems or problems of only the externalizing variety. In their sample of 51 10-year-old boys, ANS reactivity was gauged with EMG, finger pulse amplitude, and inter-beat interval of the cardiac cycle during a laboratory paradigm in which the children were rewarded for correct responses to a series of challenging arithmetic questions (the Arithmetic Stress Task, adapted from Carroll, Turner, & Hellawell, 1986). Results of the test of group differences across the psychophysiological indices revealed that boys who were both disruptive and anxious manifested significantly higher degrees of sympathetic reactivity than either the disruptive group or the controls, and the group of boys who had histories of disruptive behavior without anxiety manifested sympathetic underarousal as indexed by low levels of EDA during the cognitive stress task.

Indeed, there is an ample body of evidence to suggest that global ANS underarousal may constitute an early marker for subsequent antisocial behavior in adulthood. In a recent review, Raine (2002, p. 417) suggests that low resting heart rate "is the best-replicated biological correlate of antisocial and aggressive behavior in children." In his meta-analysis of 29 studies that examined resting heart rate and antisocial behavior in children and adolescents, the combined effect size was robust ($r = .56$), was equal in strength for both males and females, and was found across various types of measurement and in data collected across multiple countries (Raine, 1996). Raine (2002) also suggests that heart rate findings are particularly diagnostically signifi-

cant (when compared to other ANS measures), inasmuch as no other psychopathological condition is associated with low heart rate. ANS underarousal when assessed by heart rate also appears to be a strong biological marker for the condition, as it has been found to contribute *unique variance* to childhood violence beyond the effects of contextual factors such as family risk and *interacts* with psychosocial risk factors. For instance, Farrington (1997) showed that the joint effect of low resting heart rate and a poor parent-child relationship placed boys at the most risk for becoming violent offenders in adulthood. According to Raine (2002), the heart rate findings in children at risk for the development of antisocial behavior holds much promise for the advancement of current understandings regarding etiological contributions to the disorder as well as psychopharmacological treatment of violent behavior in childhood.

Recent work to uncover the ANS correlates of childhood externalizing behaviors has turned to the role of the parasympathetic branch (Beauchaine et al., 2001; Herpertz et al., 2003; Pine, Wasserman, & Coplan, 1996). In their study of aggressive behavior in children, Pine and his colleagues showed that childhood aggression was associated with increased parasympathetic reactivity, as manifest by reduced levels of vagal tone. Beauchaine and his colleagues have extended the literature in ANS reactivity and conditions of externalizing by examining the sympathetic and parasympathetic reactivity profiles of adolescent boys with ADHD with and without the comorbid condition of Conduct Disorder (CD) and normal controls. Differentiation between these two conditions is of particular relevance to understanding the ANS underpinnings of childhood aggression, as both groups are characterized by disinhibition, with aggression and antisocial behavior unique to only one group. Results of this study revealed that both clinical groups manifested less BIS activity (i.e., lower levels of EDA) relative to normal controls. Further, children with CD and ADHD showed reduced BAS activity (i.e., lengthened PEPs) relative to normal controls and children with only ADHD. Finally, children with comorbid ADHD/CD exhibited parasympathetic hyperreactivity, as evidenced by low vagal tone. Hence, results of this important study show that although BIS dysfunction is common among both groups of externalizers, reduced regulatory control in fight/flight responding and sympathetic underarousal is specific to the more aggressive, antisocial children with CD.

Herpertz and his colleagues (2003) conducted a similar study of externalizing disorder and ANS reactivity. Their study included children with an exclusive ADHD diagnosis, the comorbid ADHD/CD condition, and a group of children with an exclusive CD diagnosis, the inclusion of which per-

mitted the drawing of more definitive conclusions as to whether CD by itself is associated with autonomic dysregulation. Results of this study revealed that low resting heart rate was exclusive to the two groups of CD children, confirming Raine's (2002) contention that poorly regulated BAS activity is specific to children with aggressive and/or antisocial tendencies.

Future Directions in the Use of Autonomic Nervous System Measures

As indicated by Raine (2002), examination of ANS reactivity has led to great strides in understanding the physiological nature of childhood aggression. However, the work in this area to date is far from exhaustive for externalizing or internalizing behavior problems. For instance, Beauchaine and his colleagues (2001) have indicated that although findings regarding parasympathetic dysregulation in aggressive and antisocial behavior are promising, additional work in RSA has revealed similar patterns of dysfunction in anxiety disorders, suggesting that parasympathetic reactivity is a generalized, nonspecific marker of emotion dysregulation.

It is somewhat paradoxical that although autonomic arousal is the psychophysiological measure with the longest history, it has perhaps contributed the least to current understandings of normative and aberrant psychological development. Future work would do well to emphasize the differential role of sympathetic and parasympathetic reactivity to childhood psychopathology, as dysregulation accompanied by distinctive BIS-BAS profiles seems to underscore problems of internalizing and externalizing behaviors.

Cortisol

Beginning in the 1930s (Lovallo & Thomas, 2000), researchers have focused on the LHPA system as a central regulator of the body's metabolic stress response. The LHPA system is central to normal daily functioning in that it allows the organism to respond to external events, both positive and negative, active and sedate, while still maintaining overall functioning within the relatively narrow confines of healthy adaptation. The LHPA system is most often studied via its main glucocorticoid, cortisol (Lovallo & Thomas, 2000).

Cortisol acts as an allostatic regulator (McEwen & Lasley, 2003; McEwen & Wingfield, 2003). That is, cortisol acts to maintain physiological systems in working balance (allostasis) as they react to normal changes in functioning. This is in contrast to homeostatic regulators, which strive to bring the individual to a set point of functioning (Bauer et al., 2002). Cortisol fine-tunes multiple physiolog-

ical systems to meet continual changes in both the external and internal environments. Its impact is wide-ranging and is not simply tied to moments of high stress, as would normally be defined for research in psychopathology. For example, exercise will increase cortisol secretion if its duration challenges metabolic and cardiovascular expenditures (Sung, Lovallo, Pincomb, & Wilson, 1990).

As a daily regulator, cortisol is marked by a stable diurnal rhythm of secretion. The diurnal cycle is marked by peak cortisol levels in the early morning hours that then bottom out in the midafternoon. The magnitude of this cycle is quite extreme, such that there is often a 10-fold difference in cortisol levels between the peak and the trough (Goodyer, Park, Netherton, & Herbert, 2001). This pattern suggests that LHPA activity is providing the "wake-up energy" needed to transition from a sleep state to the active events of the day (Erickson, Drevets, & Schulkin, 2003).

The allostatic load of an environment is tied to the frequency, intensity, and predictability of the demands placed on the individual. Prolonged functioning under high allostatic load can lead to alterations in central regulatory mechanisms in terms of both daily functioning and in response to acute stressors (Johnston-Brooks, Lewis, Evans, & Whalen, 1998). This dysregulation, which is itself a form of allostatic load, may act as a causal mechanism for both psychological disorders and their behavioral precursors (Bauer et al., 2002). The impact of this type of disturbance may be particularly high in childhood given that early exposure to stress may produce lifelong effects on neuroendocrine function that may be behaviorally transmitted to future generations (McEwen, 1999).

Cortisol Methodology

In the literature, LHPA activity in children has been assessed through the use of serum cortisol, urinary cortisol (Kruesi, Schmidt, Donnelly, Hibbs, & Hamburger, 1989; Tennes & Kreye, 1985), adrenocorticotropin hormone (ACTH), and, most commonly, salivary cortisol (Schmidt, Fox, Sternberg, et al., 1999; Schmidt et al., 1997). Unlike more cumulative measures of LHPA functioning, salivary cortisol is sensitive to variations in cortisol levels throughout the day (Bauer et al., 2002). It is highly correlated with cortisol levels in the blood and cerebral spinal fluid, and, unlike with serum cortisol, collecting salivary cortisol is a benign, noninvasive process that can be used with relative ease across a wide age range. Most studies have asked children to either deposit saliva directly into a small container or have had children chew on a dry piece of cotton soaked in a sugary substance. The sample is then squeezed out of the cotton into a container for assaying.

Given that collection is relatively simple, researchers have the luxury of collecting multiple samples both within and across a period of time. Depending on the exact parameters of the study, researchers are then faced with a choice of how best to summarize and quantify LHPA activity. For example, a review of the literature indicates that studies have employed a variety of measures, including basal level, median level, daily range, reactivity to stress, pulse amplitude, and frequency. These measures capture different facets of the LHPA system's dual role: regulation and reactivity.

Each particular measure provides very different views into the relationships between the LHPA axis, behavior, and affect (Gunnar & Donzella, 2002; Tout, de Haan, Kipp-Campbell, & Gunnar, 1998). For example, Schmidt et al. (1997) found a significant positive correlation between temperamental withdrawal and basal cortisol levels. However, there were no group differences when comparing the same children after a series of startle probes. Findings such as these reflect the fact that different measures are linked to different patterns of neural activity. That is, although stress-induced cortisol is produced after an acute activation of the paraventricular nucleus of the hypothalamus, basal levels of cortisol are governed by neuronal projections originating in brain nuclei associated with biological clocks (Gunnar & Donzella, 2002).

The particular cortisol measure used may also greatly affect the strength of the available data. For example, Gunnar and Donzella (2002) argue that it is relatively difficult to elicit increases in cortisol among young children through the introduction of the mild stressors normally approved for laboratory use. Given that one cannot dramatically increase the potency of the stressors, Boyce et al. (2001) suggest expanding the way reactivity is defined. Currently, reactivity is most often defined as the difference between baseline arousal and stress-induced arousal. It may be more informative to try to capture the broader pattern of response. This includes the magnitude of the physiological response, the variability of the response, recovery time, and the ability to habituate to the triggering stimulus. Boyce (Boyce et al., 2001) has speculated that reactive children have difficulty regulating their initial arousal response and that this difficulty extends from their physiological responses to their behavioral coping strategies. To examine children's ability to dampen a response after an acute stressor, one needs to have multiple measures of cortisol after the introduction of the triggering stimulus (Ramsay & Lewis, 2003).

Cortisol and Developmental Psychopathology

Not all individuals with objectively high allostatic loads exhibit psychological distress. Individual differences in

vulnerability have been tied to differences in resting physiological arousal as well as reactivity to an environmental stimulus. The hippocampus, a central limbic structure, is considered a primary regulator of cortisol during both normal activity and periods of high stress (Jacobson & Sapolsky, 1991). It performs through negative feedback regulation, inhibiting secretion during normal functioning (shaping the nadir seen in the diurnal cycle) and in times of acute stress. In the hippocampus, it has been suggested that one set of receptors (mineralocorticoid; MR) regulates diurnal variations in cortisol levels and another (glucocorticoid; GR) regulates stress-related secretion (Dallman et al., 1987).

This division of labor is an important factor in shaping individual responses to environmental change. The diurnal cycle regulated by MR is sensitive to negative feedback, helping to ensure regularity (Munck, Guyre, & Holbrook, 1984). However, negative control of the acute GR response is weakened by strong activation of the amygdala (Lovallo & Thomas, 2000). Hyperarousal of the amygdala, in turn, is thought to play a central role in shaping the fear response in both animals (LeDoux, 1996) and humans (Kagan, 1984). In young children, it has been linked to individual differences in temperamental shyness and social withdrawal (Garcia Coll, Kagan, & Reznick, 1984). The data indicate that the LHPA axis response is not governed solely by the nature of the stressor. Rather, individual differences in stress response often result from the individual's cognitive and emotional reactions to the stimulus (Lazarus & Folkman, 1984).

The LHPA axis is one actor among an interconnected system of regulators that help the individual respond to the environment. Individual differences in the way these systems interact and respond may help our understanding of phenotypic differences in behavior. Unlike the catecholamines of the sympathetic-adrenal-medullary (SAM) system, which act quickly to generate the fight-or-flight response (Henry, 1992), the glucocorticoids produced by the LHPA axis are slow-acting steroid hormones. Cortisol must be synthesized on demand and acts by affecting protein synthesis. Cortisol is released by the adrenal cortex only after a signal from the anterior pituitary, which must, in turn, be signaled by the release of corticotropin-releasing hormone (CRH) from the hypothalamus (Bauer et al., 2002). As a result, although cortisol is released within 10 to 30 minutes after a stressor, its effects on target tissues may not be evident for over an hour (Kirschbaum & Hellhammer, 1994).

Henry (1992) has argued that the SAM system acts to generate a "defense reaction," whereas the LHPA system

activates a “defeat reaction.” The SAM system is thought to mount an effortful response to a stimulus that is considered manageable or under personal control (Peters et al., 1998). For example, individuals with a Type A personality are likely to show larger SAM responses, even as early as 3 years of age (Brown & Tanner, 1988; Lundberg, 1986). In contrast, adults show a larger LHPA response to situations that are deemed uncontrollable (Peters et al., 1998) or are likely to provoke fear and frustration (Lovallo & Thomas, 2000).

For children, the response is particularly strong if it involves a situation whose outcome they view as highly important (Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1997; Kirschbaum & Hellhammer, 1994). Lewis and Ramsey (2002) found that at age 4 children who exhibited embarrassment and shame after failure had higher levels of salivary cortisol. They argued that cortisol levels might differentially reflect stress experienced after negative evaluations. These data are also in line with the temperament literature which indicates that behaviorally inhibited children are likely to show elevated cortisol levels at baseline (Kagan, Reznick, & Snidman, 1987; Schmidt et al., 1997).

In both children and adults, the cortisol response is closely tied to individual variations in the affect-stress response. A prime example of this can be found in a growing literature indicating that the relationship between LHPA activity and behavior varies as a function of gender. To begin with, men and women appear to differ in the experiences they consider stress-inducing (A. Taylor, Fisk, & Glover, 2000). The assumption is that the stress response in women involves less sympathetic arousal, is primarily defensive, and is likely to be moderated by social context. For example, college-age women showed elevated cortisol levels after experiencing a social stressor in the form of social rejection (Stroud, Salovey, & Epel, 2002). Their male counterparts showed greater reactivity to an achievement challenge involving difficult mathematical and verbal problems. Over time, these variations in stress response may alter the relationship between basal cortisol levels and behavior.

Boys and girls also differ in how dysregulation is manifested in behavior. In general, boys are more likely to show high levels of externalizing behavior, whereas girls show more internalizing behavior (Merrell & Dobmeyer, 1996; Keiley, Bates, Dodge, & Pettit, 2000). This dichotomy suggests that the developmental role of underlying regulatory mechanisms also differs. For example, Carrion et al. (2002) found that girls with PTSD had higher basal cortisol levels than boys with equivalent levels of PTSD. Klimes-Dougan and colleagues (Klimes-Dougan, Hastings, Granger, Usher,

& Zahn-Waxler, 2001) also found differing diurnal rhythms between male and female adolescents at risk for psychopathology. This is in line with data from a nonclinical sample that LHPA activity helps sustain temperamental biases from infancy to early childhood in boys, but not girls (Pérez-Edgar, Fox, Schmidt, & Schulkin, 2004).

This is not to say that the SAM response is “good” and the LHPA response is “bad.” Indeed, Munck (Munck et al., 1984) argues that the LHPA response must step in to suppress the initial fight/flight response and prevent lasting damage to the individual by regulating sympathetically mediated changes in cardiovascular function, metabolism, and immune function (Sapolsky, Romero, & Munck, 2000). In addition, brief and periodic increases in cortisol may enhance focused attention on emotionally arousing stimuli and marshal cognitive forces for a response (Erickson et al., 2003). As such, it appears that the SAM and LHPA systems must work in tandem to provide the optimal level of arousal and attentional engagement that higher-order cognitive mechanisms rely on.

The growing consensus in the psychopathology literature holds that dysregulation of the LHPA system, often due to prolonged periods of high allostatic load, disrupts the individual’s ability to self-regulate and adapt to shifting environmental demands. This leaves the individual vulnerable to psychological maladaptation. The data, as outlined next, indicate that this mechanism may be central to psychopathology in both children and adults, playing a role in its etiology, maintenance, and perhaps intergenerational transmission.

For example, findings from the adult literature suggest that PTSD may be linked to hippocampal attrition, as seen in reduced volume (Bremner, Krystal, Southwick, & Charney, 1995; Gurvitis, Shenton, Hokama, & Ohta, 1996), decreased blood flow (Semple et al., 1993, but not Rauch et al., 1996), and poor working memory performance (Bremner et al., 1995). Both Nadel and Jacobs (1998) and Yehuda (1997) have suggested that the damage is due to stress-related steroid exposure via dysregulation in the LHPA axis. In the glucocorticoid cascade hypothesis, the presence of cortisol in GR and MR during stress negatively impacts hippocampal neurons (Lovallo & Thomas, 2000). Damage to the hippocampus, a critical feedback site, may disrupt diurnal regulation and lead to chronically high levels of cortisol, further increasing the system’s vulnerability to future stress. Along the same lines, disturbances in autobiographical memory in depressed adults have been linked to hippocampal damage due to excessive cortisol secretion (Axelson et al., 1993).

Parallel work in the developmental literature suggests that a similar mechanism may also shape behavior and

psychological adjustment in children. For example, Gunnar and Nelson (1994) found a diminished late positive component in the ERPs of 12-month-olds with high levels of cortisol, reflecting the dampening effect of cortisol on hippocampal activity and perhaps also development. Some (e.g., Goodyer, Park, Netherton, et al., 2001) have speculated that this disruption of the hippocampus will directly impact memory formation, particularly memories of an autobiographical nature, thus placing the child at risk for later difficulties (Lynch & Cicchetti, 1998; Pollak, Cicchetti, & Klorman, 1998).

Under normal circumstances, the LHPA system goes through at least two major shifts in functioning and reactivity in the 1st year of life. The first 3 months sees the emergence of the cortisol diurnal rhythm and a reduction in the cortisol response to a specific stressor. In the next 9 months, the cortisol response to nonspecific general stressors decreases again (Gunnar, Brodersen, Krueger, & Rigatuso, 1996). This buffering can be seen in the fact that routine examinations by a pediatrician will trigger a cortisol response in the young infant (Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996) but will not do so in the 2nd year of life. This developmental progression is sensitive to environmental characteristics. Indeed, the connection between early life events and later LHPA activity is sensitive to extremely subtle environmental differences. For example, 8-week-old infants who underwent an assisted delivery (e.g., forceps) show a larger cortisol response to inoculation than do infants who had vaginal or cesarean deliveries (A. Taylor et al., 2000).

Similar mechanisms may be at play for children of highly stressed or depressed mothers, shaping behavior through both biological and environmental channels. Stress during pregnancy, as measured by morning cortisol levels, has been associated with delays in motor and mental development at 8 months of age (Huizink, Robles de Medina, Mulder, Visser, & Buitelaar, 2003). Depressed mothers often provide detached and inconsistent care to their children (Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002; G. Dawson & Ashman, 2000). Unpredictability in the environment has, in turn, been suggested as a possible factor in LHPA dysfunction. In fact, depressed mothers have higher salivary cortisol levels than nondepressed mothers, and these elevations are associated with more depressed behaviors in the infants (Field et al., 1988). At age 3, children of depressed mothers displayed higher baseline cortisol levels than children of nondepressed mothers (Hessl et al., 1996). Recently, Ashman et al. examined the effect of maternal depression on offspring LHPA activity as a function of the timing of depressive episodes and found

that the presence of depression in the first 2 years of life was the best predictor of cortisol production at age 7.

Given these data, it is not hard to imagine that a prolonged disruption in a child's environment could have profound effects on allostatic load and the body's ability to self-regulate. As a relatively benign example, infants with colic show a flattening of the normal daily cortisol cycle (Finsterwald, Selig, Schieche, Wurmser, & Papousek, 2000; B. P. White, Gunnar, Larson, Donzella, & Barr, 2000), which may reflect the toll of persistent crying and the disruption to normal daily events (e.g., colicky babies tend to have bouts of interrupted sleep).

In general, the literature indicates that children with severe difficulties in their caretaking environment have either chronically high cortisol levels or unusually low basal cortisol levels with occasional spikes (Flinn & England, 1995). Chaotic or unpredictable schedules also contribute to the blunting of the normal diurnal rhythm (Gunnar & Vazquez, 2001). For example, maltreatment and abuse may produce chronic disruptions of the LHPA axis and play a central role in the development of psychopathology. DeBellis et al. (1999) found that cortisol concentrations in abused children were positively correlated with the duration of trauma and the intensity of symptoms in children subsequently diagnosed with PTSD. Indeed, Cicchetti and Rogosch (2001) found that cortisol patterns also reflected the form of the abuse experienced by the child. Carrion et al. (2002) found that young children with PTSD exhibited elevated basal cortisol levels and a flattening of the diurnal cycle.

To date, most studies have assessed outcomes in two broad categories: internalizing and externalizing behavior. Studies generally look at either one form of behavior or the other. When included in a single study, internalizing and externalizing behaviors are often treated as orthogonal to each other, despite the fact that these behaviors are often highly related (e.g., Granger, Weisz, & Kauneckis, 1994).

In general, the data indicate that low LHPA activation is associated with externalizing, aggressive, or disruptive behavior in children (McBurnett et al., 1991; Tout et al., 1998). For example, Van Goozen et al. (1998) had boys ages 8 to 11 diagnosed with Oppositional Defiant Disorder (ODD) or CD participate in a competitive stressor. Compared to the control children, the boys with ODD/CD had lower baseline levels of cortisol. However, there were no differences in stress-induced cortisol across groups. Pajer and colleagues (Pajer, Gardner, Rubin, Perel, & Neal, 2001) found a similar relationship between low resting cortisol and externalizing behavior in a group of 15- to 17-year-old girls diagnosed with CD.

In contrast to externalizing behavior, internalizing problems have been linked to higher levels of adrenocortical activation in children (Ashman et al., 2002; Gunnar, Tout, de Haan, Pierce, & Stansbury, 1997; Kagan, Reznick, & Snidman, 1988; Schmidt et al., 1997). For example, Granger et al. (1994) found that among a group of clinic-referred children, those with the highest levels of cortisol reactivity displayed more internalizing behavior (social withdrawal and anxiety) than the children with low reactivity. Similarly, children with clinically significant levels of internalizing difficulties show significantly larger cortisol responses to a mild stressor in the form of a potentiated startle (Ashman et al., 2002). Granger et al. also found that a continuous measure of cortisol activity predicted over-controlled behaviors, defined as a composite of social withdrawal, anxiety, depression, and somatic complaints. This is in line with data indicating that temperamentally inhibited children also show higher cortisol levels at rest (Kagan et al., 1987).

However, there are indications that this pattern of data is not universal. For example, some studies have shown a positive correlation between cortisol levels and externalizing behavior. Tout et al. (1998) observed children at playtime in a preschool and found that increased cortisol reactivity (a measure reflecting the tendency to have frequent high morning cortisol levels) was associated with angry and aggressive behaviors. Recent findings also suggest that normally developing preschoolers showing high levels of cortisol are higher in both internalizing and externalizing difficulties 2 years later at the end of first grade (Essex, Klein, Cho, & Kalin, 2002).

In addition, Gunnar and Vazquez (2001) have argued that young children at risk for psychopathology often exhibit lower basal cortisol levels, not higher levels, as would be expected. The accompanying flattening of the diurnal cycle in these cases is due to lower cortisol levels in the morning, the normal peak in the cycle, rather than higher levels at the trough, as is often seen with depressed adults. Also evident in this pattern of "hypocortisolism" is a blunting of the cortisol stress response to an acute trigger (Heim, Ehler, & Hellhammer, 2000). Henry (1993) suggests that hypocortisolism in response to stressors may be associated with a lack of ego involvement, repression or passive coping, and emotional indifference. Hypocortisolism may also reflect chronic allostatic adjustments (McEwen, 1998), often seen as an extended period of elevated cortisol in response to trauma or stress (Hellhammer & Wade, 1993). Granger et al. (1998), for example, found that children under chronic stress had subnormal cortisol levels in nonstressful conditions.

Indeed, the most dramatic example of hypocortisolism can be found in environments marked by maltreatment, neglect, and natural or sociopolitical disaster, including children reared in orphanages (Carlson & Earls, 1997), cloth-reared monkeys (Boyce, Champoux, Suomi, & Gunnar, 1995), and adolescent survivors of earthquake with subsequent symptoms of PTSD (Goenjian et al., 1996). Yehuda (Yehuda, Boisoeneau, Mason, & Giller, 1993; Yehuda, Southwick, et al., 1993) has argued that hypocortisolism may be due to early life stresses that result in a negative regulation of the LHPA axis, which may in turn create an inability to effectively deal with subsequent stressors.

The studies reviewed so far indicate that disruptions in the child's environment may disrupt LHPA functioning and place the child at higher risk for psychopathology. Studies focused on childhood depression illustrate the consequences of LHPA dysfunction on subsequent development.

Goodyer and colleagues (Goodyer, Herbert, Tamplin, & Altham, 2000a, 2000b) have found that among healthy adolescents at high risk for depression there is a high correlation between cortisol levels and subsequent diagnoses of Major Depression. In addition, approximately one-quarter of children and adolescents with depression show elevated cortisol levels (Rao et al., 1996). For example, Goodyer and colleagues (Goodyer, Park, & Herbert, 2001) followed a group of clinically depressed 8- to 16-year-olds across a 72-week period, collecting morning and evening cortisol samples for two consecutive days at three points in the study: inception, 36 weeks, and 72 weeks. Those children whose symptoms had not diminished were classified as chronically depressed. The other children were placed in the recovery group. At each of the collection points, the children in the chronically depressed group had higher evening cortisol levels than the children in the recovered group.

In addition, Goodyer, Park, and Herbert (2001) found that adverse life events over the course of the study were associated with elevated cortisol levels at inception. They speculated that cortisol hypersecretion might affect cognitive processes that influence risk for adverse events. Indeed, there are initial indications (E. P. Davis, Bruce, & Gunnar, 2002; Vedhara, Hyde, Gilchrist, Tytherleigh, & Plummer, 2000) that LHPA activity may be related to both the development and current functioning of the prefrontal cortex, specifically the anterior cingulate cortex (ACC). Poor prefrontal functioning has, in turn, been linked to the appearance of behavioral maladjustment (Bush et al., 1999; E. P. Davis et al., 2002) and poor or risky decision making. Given that the ACC is undergoing significant maturation during childhood (Janowsky & Carper, 1996; Rothbart, Posner, & Hershey, 1995), one may speculate

that this process may impact the observed relationship between cortisol and behavior. Unfortunately, the extant literature cannot at this time address basic questions concerning the direction of the effect and the potential causal bases.

Future Directions in the Use of Cortisol

For the most part, studies examining the relationship between cortisol and psychopathology have relied on two basic measures: baseline cortisol and acute cortisol after the introduction of a stressor. These measures have added to our understanding of the impact of the LHPA system on affect and behavior. However, recent work suggests that an additional quantification of LHPA functioning may greatly help. That is, an examination of variations in the diurnal cycle may allow researchers to examine the *shape* of the cortisol cycle in response to environmental challenges (Gunnar & Vazquez, 2001). An example of this research strategy can be found in the child care studies overseen by Gunnar and her colleagues.

A number of studies have now noted that children in full-time center-based child care often show an increase in cortisol levels throughout the day (Tout et al., 1998; Wata-mura, Sebanc, & Gunnar, 2002), rather than the expected dip in cortisol seen in children tested in the home setting (Wata-mura, Donzella, Alwin, & Gunnar, 2003). Wata-mura et al. (2003) note that cortisol increases appear to emerge in infancy, peak in the toddler years, and disappear by the early school years. The available data suggest that the increase in cortisol is linked to the increasing social demands and complexity of the child's environment as he or she moves from infancy into toddlerhood (Dettling, Gunnar, & Donzella, 1999; Tout et al., 1998; Wata-mura et al., 2003). The subsequent downturn in the trend is presumably due to the child's increasing ease when engaged in social interactions.

The data also suggest that the developmental trends in cortisol production are context-specific. That is, children appear to revert to the "normal" cortisol rhythm when not in the child care setting (Wata-mura et al., 2003). Because older children in full-day child care also show the expected dips in afternoon cortisol levels, it does not appear that mild environmental challenges, even if relatively frequent, permanently alter the diurnal cortisol pattern. This is in contrast to the abuse and maltreatment literature, which finds that prolonged adversity can flatten the diurnal cycle (Carrion et al., 2002). As such, these data point to the importance of noting individual differences in both context and developmental state when examining cortisol production throughout the day. In this way, research may be better

able to capture both the regulatory and reactive functions of the LHPA axis.

Electroencephalogram

The use of EEG to assess human behavior and development began quite early with the work of Berger (1929, 1932). Although the first reports were met with skepticism, the measure was soon widely accepted in the biomedical research community, particularly after a live demonstration at a 1935 meeting of the Physiological Society in London convinced people of its usefulness (Davidson, Jackson, & Larson, 2000). Much of the early work was hampered by the fact that reports were largely descriptive, used adult indices of behavior (e.g., alertness) even when dealing with children and infants, and were reliant on cumbersome, and perhaps inaccurate, manual analyses of the EEG data (e.g., J. R. Smith, 1938a, 1938b, 1938c).

Many of the methodological issues limiting the early research were beginning to subside by the 1960s, when Hagne and colleagues (Hagne, 1968, 1972; Hagne, Persson, Magnusson, & Petersén, 1973) began their longitudinal studies of EEG development. The introduction of quantitative EEG analysis through the use of computers and the fast Fourier transform greatly increased the scope of data available to the researcher. These include waveform amplitude (Matousek & Petersén, 1973), absolute and relative power (Clarke, Barry, McCarthy, & Selikowitz, 2001c), dominant and subordinate frequency analysis (Katada & Koike, 1990), mean frequency (Chabot & Serfontein, 1996), the wave percentage time (Matsuura et al., 1985), EEG asymmetry (Davidson, 1995), and the coherence of the EEG signal across regions (Chabot & Serfontein, 1996; Thatcher, 1992).

Taking advantage of these technological advances, Hagne was able to emphasize the importance of changes in relative power and peak frequency. For example, she found that the ratio between delta (1.5 to 3.5 Hz) and theta (3.5 to 7.5 Hz) frequency changes between 8 and 12 months of age due to an increase in theta and a decrease in delta (Hagne, 1968, 1972). These shifts in relative power were then linked to patterns of change in behavior.

In addition to examining normal functioning and development, the use of EEG measures to examine psychopathology in adults and children began fairly early. P. A. Davis and Davis (1939), for example, collected resting EEG from a large sample of psychotic adults and found that the patients demonstrated significantly less alpha activity than did control subjects. Later studies also found a similar pattern in

anxious adults (Duffy, 1962). Investigations of ADHD, then known as minimal brain dysfunction syndrome, began in the 1930s (Jasper, Solomon, & Bradley, 1938).

Linked to a relatively long history of EEG experimentation, the past 3 decades have seen exponential growth in the use of EEG measures in psychological research. This section reviews the collection and interpretation of the EEG signal, our current understanding of the normal developmental progression, and its application to the study of developmental psychopathologies.

Electroencephalogram Methodology

EEG is collected via electrodes placed on the scalp either singly or by group as part of a net or cap system. Distributed in a standard placement design (Jasper, 1958), the electrodes are referred to by the cerebral lobe their scalp locations are closest to (e.g., F = Frontal, P = Parietal) and their relative location on the scalp (Odd numbers = Left hemisphere, Even numbers = Right hemisphere, z = Midline). The electrical activity recorded via the electrodes is referenced to relatively inactive electrode site(s), and the signal is then saved offline for further processing and analysis. The collected signal is thought to be derived from the summation of postsynaptic potentials. This rhythmic electrocortical activity is regulated by the thalamus (Larson, White, Cochran, Donzella, & Gunnar, 1998), particularly through the nucleus reticularis (Steriade, Deschenes, Domich, & Mulle, 1985).

Before statistical analyses begin, EEG power is normally aggregated across frequency bins to form measures of band power. Different epochs of the same condition are then averaged to provide more reliable estimates of spectral power, in much the same way as behavioral reaction time data. A more detailed discussion of the steps involved in EEG collection and processing can be found in Davidson, Jackson, et al. (2000) and Pivik et al. (1993).

EEG data are primarily characterized along the dimensions of amplitude and frequency, which are often used to describe the differences across major behavioral states (Pillgreen, 1995). In adults, deep sleep is associated with large and very slow waves in the delta frequency range (1 to 4 Hz). Drowsiness is characterized by reduced amplitude theta activity (5 to 7 Hz), although delta activity is also common. Alpha activity (8 to 13 Hz) is often linked to a state of “relaxed wakefulness,” and points of high alert and attention are marked by low-amplitude fast activity (>13 Hz). Much of the literature has focused on quantifying alpha activity in response to experimental task manipulations.

EEG measures have proven particularly attractive in the laboratory because the signal derived has good temporal

resolution, in the realm of milliseconds. Indeed, EEG can detect neuronal changes in activity almost instantaneously (Davidson, Jackson, et al., 2000). This is particularly important when dealing with processes that are fast-acting, irregular, and spontaneous, such as emotion. Behaviors that are fleeting (lasting only a second) can be easily detected given that EEG is often sampled 200 times per second. This compares favorably with the long lag times found with functional MRI (fMRI) and PET, compensating for the relatively poor spatial resolution seen in the EEG signal.

On this point, Davidson, Jackson, et al. (2000) argue that even when using high-density electrode arrays, which can collect data from up to 256 sites (compared to traditional 16- and 32-channel collection protocols), EEG recording will always lag behind metabolic and hemodynamic imaging. This is due in part to spatial resolution a full order of magnitude coarser than that found with fMRI, the distortion produced via transmission through the skull, and the fact that a particular distribution of scalp potentials can be produced by different combinations of neuronal generators.

In addition, there are some methodological concerns in collecting EEG that are common when dealing with children. First, the validity of EEG data is dependent on the analysis of a clean signal that is free of motor or movement artifact and was generated under the specific mental states of interest (e.g., at rest or alert attention). However, one cannot instruct infants and young children to either sit still or focus attention solely on the stimuli of interest. As such, researchers rely on both methodological creativity and analytical skill in circumventing these difficulties. For example, Fox (e.g., N. A. Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; N. A. Fox et al., 1995) presents infants with a spinning bingo wheel filled with colorful balls to capture the infant’s attention and minimize extraneous movement. For analysis, these data are then processed to remove any movement artifacts. Even when the difficulties with artifact and attention are minimized, however, there remain concerns over the meaningfulness of the underlying data.

N. A. Fox, Schmidt, and Henderson (2000) point out that electrode placement protocol agreed on for adults (Jasper, 1958) is not necessarily appropriate for use with young children. First, it is not clear if the ratio of distances across electrode sites is stable across development, indicating that our measures may not correspond to the actual geometry or topography of the brain. Second, morphological changes in the brain throughout development may shift the location from which electrical activity is emanating. This would greatly complicate the already thorny issue of localizing the source of the EEG signal.

In documenting the change in EEG functioning over time, a number of researchers caution against using absolute power (Benninger, Matthis, & Scheffner, 1984). In particular, changes in bone thickness, skull resistance, and impedance may distort absolute power values. Instead, relative power may have better test-retest reliability (John et al., 1980) and may be more sensitive to changes in the frequency composition of the EEG with age (Clarke, Barry, McCarthy, & Selikowitz, 2001a). Relative power is expressed as the percentage of power in a specific frequency bin at each electrode site relative to total power (in all frequency bins) at the same electrode site (Marshall, Bar-Haim, & Fox, 2002).

Despite these limitations, the ease of assembling and using the equipment necessary for EEG collection, and its noninvasiveness, has made it a common tool for psychophysiological research with individuals of all ages. This has allowed researchers to document the major developmental changes that take place between the burst-suppression non-state-dependent EEG patterns seen in premature infants (less than 28 weeks conceptual age) and the organized and coherent patterns seen in normal adults. An example can be seen in Marshall et al.'s (2002) study of changes in relative power and peak frequency in children from ages 4 months to 4 years (see Figures 9.1 and 9.2).

In the 1st year of life, activity in the lower frequencies (delta and theta) decreases, whereas alpha activity increases into early adolescence and beta continues to mature into adulthood (M. J. Taylor & Baldeweg, 2002). Indeed, the normal adult EEG pattern is usually not established until 25 to 30 years of age, a point in time that corresponds to the final state of myelination (Pilgreen, 1995). The alpha band, central to many studies, migrates from the 3 to 5 Hz band in the 1st year to 6 to 9 Hz in early childhood and later settles into the 8 to 13 Hz band in adulthood (Marshall et al., 2002). Throughout the process, the rate of maturation is at its most rapid in the posterior sites and its slowest in anterior locations (Benninger et al., 1984; Gasser, Jenzen-Steinmetz, Sroka, Verleger, & Mocks, 1988).

Electroencephalogram in the Study of Developmental Psychopathology

Building on these developmental data, quantitative measures of EEG have been used to examine a number of core cognitive (Bell & Fox, 1994) and emotional (G. Dawson, Panagiotides, Grofer Klinger, & Hill, 1992) processes. In both domains, the strategy has been to create a functional link between changes in behavioral performance and the purported underlying neural mechanisms by noting changes in electrocortical signals thought to reflect activity in these same neural mechanisms.

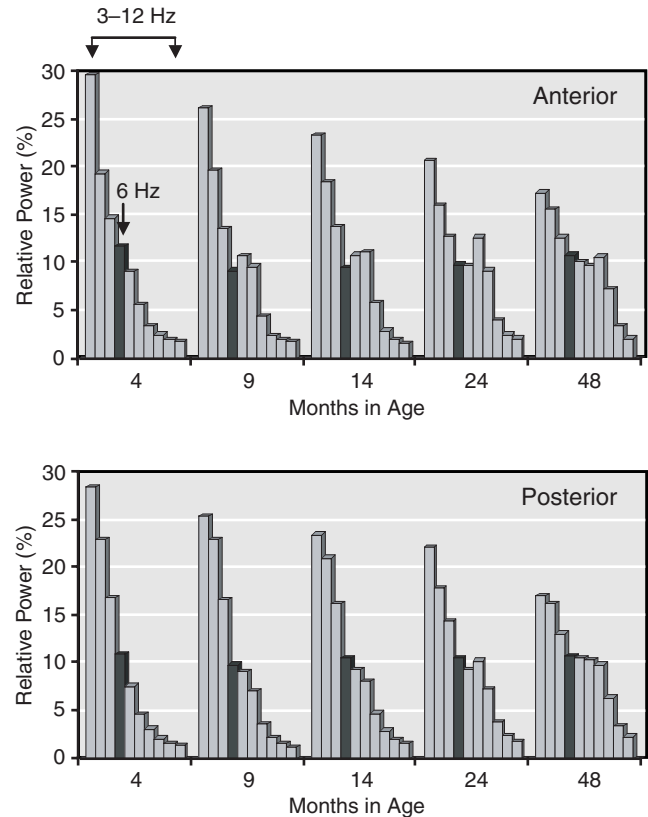

Figure 9.1 Power spectra for relative power in the 3 to 12 Hz bins for anterior (F3, F4, C3, C4) and posterior (P3, P4, O1, O2) electrode sites between 4 and 48 months of age. The 6 Hz bin is indicated in black. Adapted from “Development of the EEG from 5 Months to 4 Years of Age,” by P. J. Marshall, Y. Bar-Haim, and N. A. Fox, 2002, *Clinical Neurophysiology*, 113, pp. 1199–1208.

Early on, this work was hindered by the belief that many of the brain regions of interest were not well developed in childhood. The frontal cortex is directly involved in a number of the components underlying higher-order cognition and emotion, including the facilitation of emotional expression, the organization of cognitive processes associated with emotion, and the ability to regulate emotion (G. Dawson, 1994; N. A. Fox et al., 2000). However, the general consensus had long been that there was minimal frontal lobe development until middle childhood (Bell & Fox, 1992). As a result, much of our understanding of the relationship between EEG and development was limited to posterior sites. However, a number of studies have demonstrated that changes in frontal lobe activity occur as early as the 1st year of life (Chugani & Phelps, 1986; N. A. Fox & Bell, 1990), although frontal lobe development does lag behind growth in other brain regions. These studies further emboldened researchers to incorporate these tools in their

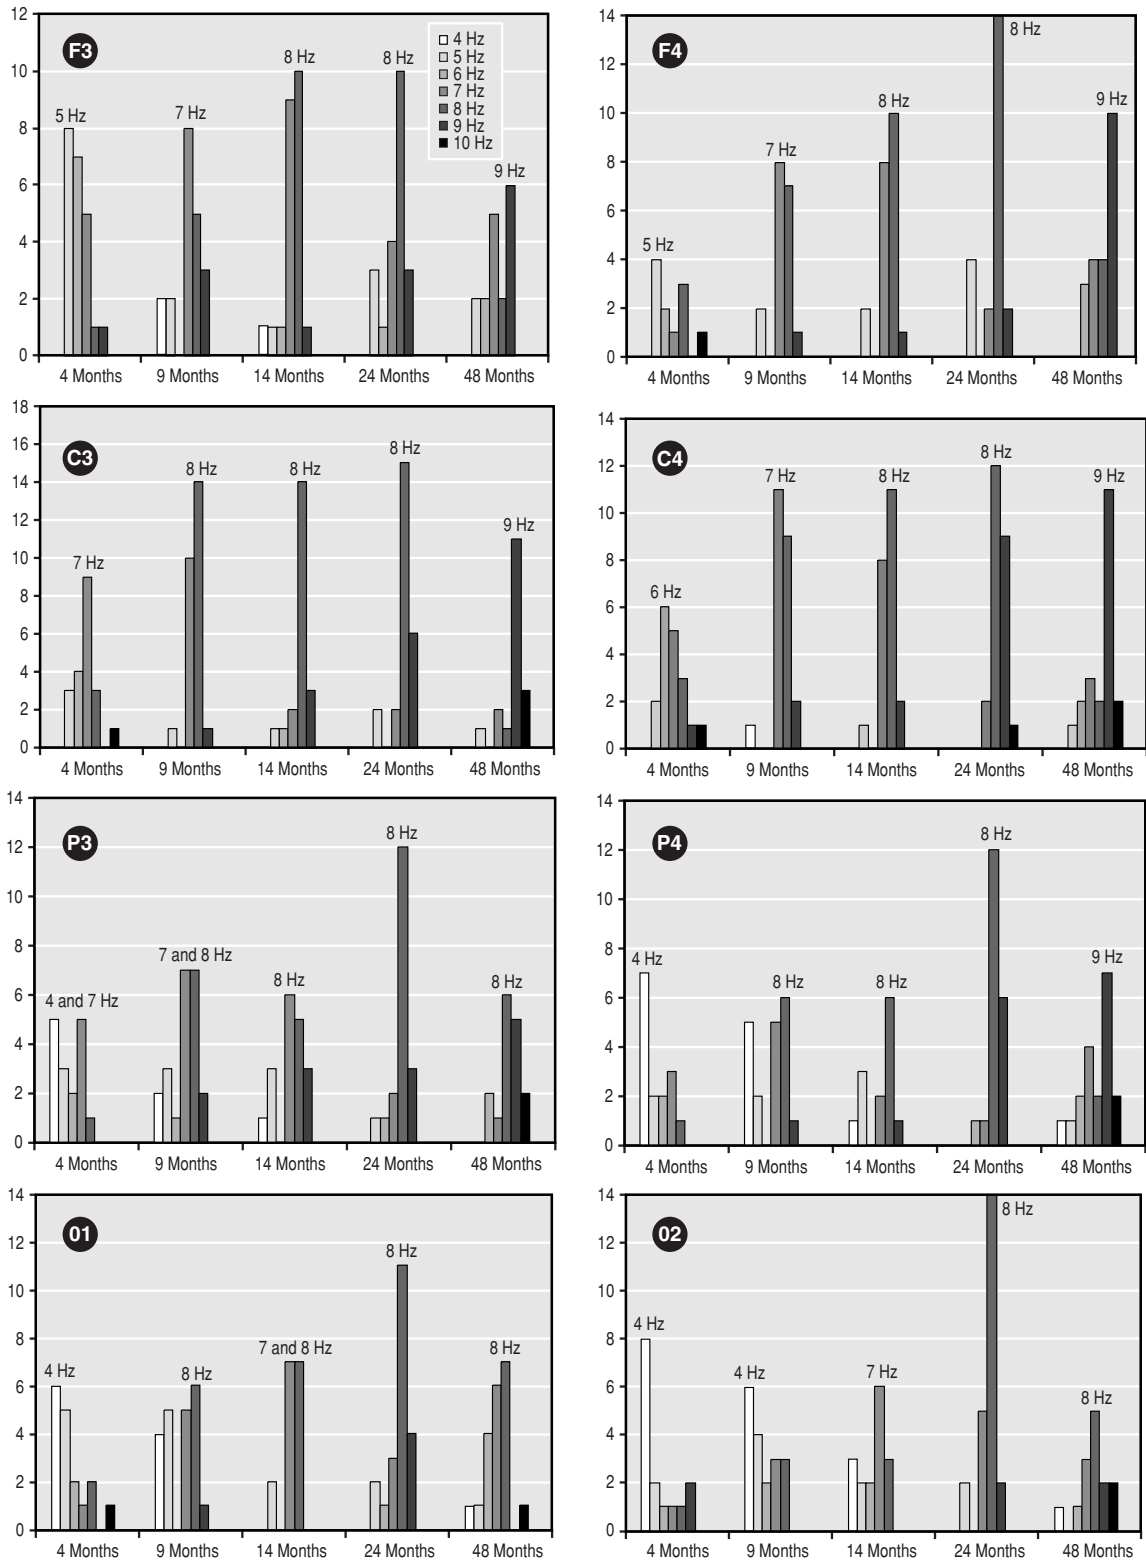

Figure 9.2 The distribution of the peak frequency of relative power within the 3 to 10 Hz range in the first 4 years of life. The bars indicate the number of participants whose peak frequency fell in each 1 Hz bin. Modal frequencies are indicated for each site and age. Adapted from “Development of the EEG from 5 Months to 4 Years of Age,” by P. J. Marshall, Y. Bar-Haim, and N. A. Fox, 2002, *Clinical Neurophysiology*, 113, pp. 1199–1208.

work. For example, Bell and Fox observed infants performing the A-not-B task monthly from ages 6 to 12 months. Their data provided added support to the notion that A-not-B performance is linked to dorsolateral prefrontal cortex development by showing a significant correlation between EEG power recorded from the frontal sites and performance on the task.

In addition to power and frequency, EEG coherence has proven to be an important tool in assessing early brain development. Coherence quantifies the phase relationship between two processes at a specific frequency band. Coherence can range from 0 (there is no phase relationship) to 1 (the two signals are either completely in or out of phase with each other). Coherence measures will shift over time depending on age and the processes of interest. For example, Thatcher (1992; Thatcher, Walker, & Giudice, 1987) has found that over time there is increased communication between anatomically distant locations, coupled with an increased differentiation across the cortex. These changes may be due to either the activity level of axonal connections across two regions (Nunez, 1981) or the activity of short- and long-fiber networks or the axons (Thatcher, Krause, & Hrybyk, 1986; Thatcher et al., 1987).

Thatcher (Thatcher et al., 1987) has argued that changing patterns of EEG coherence coincide with major points of transition in cognitive growth, providing neural mechanisms by which to explain observed behavioral differences. For example, Bell and Fox (1996) found that EEG coherence in infants who had moderate amounts of experience crawling was higher than in infants with either no crawling experience or who were proficient crawlers. It appears that the increase in coherence coincided with a period of time during which a new, core skill was being consolidated, requiring the coordination of multiple systems. Once mastered, the newly efficient process no longer required as complex a neural substrate for performance.

Beyond EEG findings in normative development, a number of studies have examined the EEG correlates of psychopathology in children and adults. For example, studies in depression indicate that the thalamocortical regulation of EEG rhythm (particularly alpha power) normally seen in adults is disrupted in individuals with depression (Lindgren et al., 1999). This is evident during sleep, which is marked by elevated levels of fast-frequency EEG (>16 Hz) and a reduction of low-frequency activity (Armitage, Hudson, Trivedi, & Rush, 1995) in depressed adults. These findings are of particular interest because sleep disturbances and abnormalities are linked to increased risk for relapse (Giles, Jarrett, Biggs, Guzik, & Rush, 1989) and suicide (Fawcett et al., 1989).

In the developmental literature, the most extensive empirical work has been done with children diagnosed with ADHD. Typically, studies find that children with ADHD have decreased alpha and beta activity most apparent in posterior sites (Chabot & Serfontein, 1996; Clarke et al., 2001c; Lazzaro et al., 1998). In contrast, there is often increased frontal theta (Clarke et al., 2001c; Lazzaro et al., 1998) and posterior delta (Clarke et al., 2001c) activity. The findings are most acute in children who show signs of hyperactivity, as opposed to inattentiveness (Clarke et al., 2003). These data have been interpreted as indicating that children with ADHD are cortically hypoaroused (Lubar, 1991) or have a maturational lag in central nervous system development (Clarke, Barry, McCarthy, & Selikowitz, 1998). The latter interpretation is bolstered by coherence data indicating that children with ADHD show less cortical differentiation than their non-ADHD peers (Barry, Clarke, McCarthy, & Selikowitz, 2002; Chabot & Serfontein, 1996). A thorough review of the EEG literature with ADHD can be found in Barry, Clarke, and Johnstone (2003).

Future Directions in the Use of Electroencephalogram

EEG studies in young populations have focused on children with learning or attention disorders (Barry et al., 2003; Marshall, Fox, & BEIP Core Group, 2004). These studies have generally found increases in low-frequency spectral power (e.g., delta and theta) and decreases in high-frequency spectral bands (e.g., alpha or beta). Until recently, very few studies have examined the effects of environment or sociocultural risk on EEG functioning. Among these studies, it appears that environmental deprivation may keep theta and delta power levels elevated beyond the normal developmental period (Harmony et al., 1988; Harmony, Marosi, Diaz de Leon, Becker, & Fernandez, 1990), whereas enrichment may depress theta and delta power (Raine et al., 2001). Given the extensive behavioral data indicating the effects of adverse environments, such as maternal depression (Field et al., 1988; G. Dawson & Ashman, 2000), institutionalization (Carlson & Earls, 1997), and abuse (Cicchetti & Toth, 1995), on socioemotional development, this appears to be an important avenue of study that could benefit from the introduction of EEG measures.

For example, Marshall et al. (2004) compared resting EEG in a group of institutionalized infants in Bucharest, Romania, to age-matched children living with their families in the greater Bucharest area. They found that the children in the institution showed more relative power in the lower-frequency bands and less relative alpha power than their community-based counterparts. In light of similar

data from children with ADHD (Barry et al., 2003) and Autism (G. Dawson, Klinger, Panagiotides, Lewy, & Castellow, 1995), it may be that EEG activity across power bands may serve as a marker for deviations or lags in development that are common to a variety of disorders or contexts (Marshall et al., 2004). This is in line with Keller et al.'s (2000) note that EEG power is multidetermined and driven by a number of summing and overlapping mechanisms. Comparisons across groups and contexts, such as those noted here, may allow us to better delineate the functional significance of resting EEG activity.

MEASURES OF MOTIVATION AND EMOTION

The use of psychophysiological methods to study emotion and motivation are relevant to the study of developmental psychopathology, particularly for disorders of affect and disinhibition. Measures covered in this section tap into the physiological substrates of the neural fear system and of the appetitive/aversive motivational systems and include EEG asymmetry and affective modulation of the startle reflex.

Electroencephalogram Asymmetry

Like the ERP, EEG asymmetry is derived from measures of raw EEG power, and, like the ERP, measures of the relative difference in activation across sites provide an additional perspective on the links between physiology and behavior. In particular, differences in EEG asymmetry have been used to examine individual differences in motivation systems both as a stable individual trait and in response to transient environmental characteristics. Indeed, the relative difference in activation across sites may be more important in determining behavior than the absolute amount of activation in a region (Davidson, Chapman, Chapman, & Henriques, 1990). This is borne out in part by the very extensive literature linking asymmetries in EEG activity to individual differences in affect in both healthy and clinical populations.

Electroencephalogram Asymmetry Methodology

EEG asymmetry is normally calculated by comparing power in two homologous electrodes (e.g., F3 and F4). Frontal EEG asymmetry is determined by subtracting the natural log of alpha power seen in the left electrode from the natural log of the alpha power in the right electrode ($\ln F4 - \ln F3$). Because EEG power is inversely related to activation, a negative number indicates that an individual is showing more activity in the right frontal lobe relative to

the left (Davidson, Jackson, et al., 2000). It is also important to note the level of activity within each lobe as this will help to explain the pattern (e.g., hyper- or hypoactivation in a particular location across individuals or conditions) underlying a particular asymmetry finding (Schmidt, 1999).

Electroencephalogram Asymmetry and Developmental Psychopathology

Davidson (1984a, 1984b, 1995) and others have argued that resting frontal EEG activation reflects an underlying motivation bias to respond to the environment in a particular hedonic manner. Individuals with right frontal EEG asymmetry are more likely to respond to the environment with negative or withdrawal emotions and behavior. In contrast, individuals showing left frontal EEG asymmetry are more likely to exhibit positive or approach responses. For example, studies have found that adults who display a pattern of greater right frontal asymmetry at rest rate film clips more negatively (Tomarken, Davidson, & Henriques, 1990) and are less sociable in a dyadic interaction (Schmidt & Fox, 1994) than are individuals with left frontal EEG asymmetry at rest.

Schmidt (1999) found that female undergraduates who rated themselves as high in shyness were likely to show right frontal EEG asymmetry due to left frontal hypoactivation. Their sociable counterparts, on the other hand, displayed more left frontal asymmetry. Schmidt further decomposed the data to compare participants who were high in shyness but varied in their level of sociability. He found that these two groups differed in the absolute power in the left frontal lobe, suggesting that there may be different types of shyness distinguishable at the behavioral (Cheek & Buss, 1981) and psychophysiological (Schmidt & Fox, 1994) levels.

Work by Tomarken and colleagues (Tomarken, Davidson, Wheeler, & Kinney, 1992) suggests that differences in asymmetry observed across individuals are rooted in functional, not structural, differences in the brain. As such, EEG asymmetry reflects functional changes in activity as well as underlying motivational biases. For example, individuals who show a pattern of left frontal asymmetry at rest may display right frontal asymmetry when presented with aversive film clips (Jones & Fox, 1992; Tomarken et al., 1990).

Adults who exhibit a stable pattern of right frontal EEG asymmetry over the course of 3 weeks report more intense negative affect when presented with negative emotional film clips (Wheeler, Davidson, & Tomarken, 1993). Participants in the same study who displayed stable left asymmetry reported more intense positive emotion when presented with positive film clips. It appears that stable patterns of

asymmetry do not simply increase general arousal, creating more intense affective responses across the board. Rather, the motivational or processing bias appears to be limited to a particular region in the affective spectrum.

EEG asymmetry may serve as a psychophysiological marker of risk for maladaptive behaviors and psychopathology. Right frontal EEG asymmetry appears to be linked to difficulty in regulating negative arousal, a bias toward negative affect, and the display of withdrawal behaviors when confronted with threat—factors that are all related to psychopathology and maladaptation.

In the adult literature, depressed individuals display less left frontal activation (Henriques & Davidson, 1991) and greater right frontal activation (Henriques & Davidson, 1990) than nondepressed individuals. Supplementing the frontal asymmetry literature, Heller (1993) has suggested that emotional functioning may also be modulated by activity in posterior brain regions. Specifically, Heller has found that depressed individuals show less EEG activity in right parietal sites. This has been replicated in a number of studies with varying experimental tasks (e.g., Bruder et al., 1995; Keller, Deldin, Gergen, & Miller, 1995) and is thought to reflect the hypoarousal often found in depression (Heller & Nitschke, 1997).

Anxiety has also been linked to greater right frontal activity, specifically in Panic Disorder (Reiman, Raichle, Butler, Herscovitch, & Robins, 1984), Generalized Anxiety Disorder (Wu et al., 1991), social phobia (Davidson, Marshall, Tomarken, & Henriques, 2000), and nonclinical individuals self-rated as high in trait anxiety (Reivich, Gur, & Alavi, 1983). Here, the direction of the effect indicates that anxiety is marked by elevated levels of negative affect and withdrawal tendencies, coupled with increased autonomic arousal. This is borne out in data indicating increased EEG activity in parietal sites (Heller, 1993).

Paralleling the adult literature, a similar pattern of frontal EEG asymmetry has been found in the 1st year of life. Davidson and Fox (1982) found that 10-month-old infants were more likely to show left frontal asymmetry when viewing a person smiling than when presented with the same individual crying. Infants of the same age also show shifts in EEG asymmetry in response to the approach of an unfamiliar adult (N. A. Fox & Davidson, 1987) and maternal separation (N. A. Fox & Davidson, 1988).

EEG measures at baseline also predict later behavior, such that infants with right frontal asymmetry will cry sooner to maternal separation than will infants with left frontal asymmetry (Davidson & Fox, 1989). In early childhood, children with right frontal asymmetry are also more

likely to be behaviorally inhibited and show difficulty with social interactions (e.g., N. A. Fox et al., 1995, 2001). Infants who displayed a stable pattern of right frontal asymmetry across time also show a stable pattern of behavioral inhibition across progressively larger time windows of 2 (N. A. Fox, Calkins, & Bell, 1994), 4 (N. A. Fox et al., 2001), and 7 years.

Henderson, Fox, and Rubin (2001) found that infant temperament predicted social wariness in early childhood only for those children who displayed a pattern of right frontal EEG asymmetry in infancy. School-age children asked to prepare a potentially embarrassing speech, a task designed to elicit social stress, showed increases in right frontal EEG asymmetry that paralleled increases in anxiety (Schmidt, Fox, Schulkin, & Gold, 1999). Baving, Laucht, and Schmidt (2002) assessed EEG asymmetry in anxious children at ages 8 or 11 relative to nonanxious control groups and found that anxious girls showed more right frontal asymmetry.

In addition, parallel data indicate that children who consistently display high levels of sociability in the first 4 years of life were more likely to exhibit left frontal EEG asymmetry (N. A. Fox et al., 2001). However, increased sociability, when coupled with right frontal EEG asymmetry, may place a child at increased risk for externalizing behavior problems (N. A. Fox, Schmidt, Calkins, Rubin, & Coplan, 1996).

Future Directions in the Use of Electroencephalogram Asymmetry

EEG asymmetry has been used to examine both individual and group differences in motivational and affective biases. The measure has provided a theoretically grounded and empirically supported mechanism by which to gauge trait- and state-based variations in a core psychological construct. Future work, while continuing on this path, will also need to examine secondary measures that may moderate the relationship between EEG asymmetry and behavior. As an example of exogenous and endogenous factors that may shape individual differences in EEG asymmetry, our discussion now briefly turns to the effects of parental characteristics (exogenous) and gender (endogenous) on the relationship of interest.

Psychopathology in children arises from multiple factors, including temperament, environmental characteristics, and parenting. As a result, developmental outcomes must be placed in the context of development to be fully understood. Based on this understanding of pathogenesis, a great deal of research has focused on the impact of maternal depression on infant physiology and behavioral outcomes. Women who are depressed display less positive

affect toward their infant, provide less stimulation (Field et al., 1988; Jones, Field, & Davlos, 2000), and often display unpredictable response patterns to their child's distress (G. Dawson & Ashman, 2000). Infants of depressed mothers, who are at a greater risk for future disorders (e.g., Murray & Cooper, 1997), display less positive affect and increased irritability (Cohn, Matias, Tronick, Connell, & Lyons-Ruth, 1986; Field, 1986; Field et al., 1985) and show greater frontal activation (Field, Fox, Pickens, & Nawrocki, 1995; G. Dawson, Grofer Klinger, Panagiotides, Hill, & Spieker, 1992) than do infants with nonsymptomatic mothers. In early childhood, these children are also more likely to show greater levels of behavioral maladaptation, particularly internalizing problems (Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002).

These data indicate that parental characteristics shape psychophysiology in the first years of life, although we do not have the research needed to determine the relative importance of environmental and heritable factors. However, it does appear that the effects of exposure to risk factors for later maladaptation are evident within the individual very early, perhaps within the first 3 months of age (Field et al., 1995). These effects have also been shown to carry on into early childhood, such that preschoolers with depressed mothers show greater right frontal EEG asymmetry and manifest less empathic responses to distress in others (Jones et al., 2000).

In terms of endogenous factors that may affect the link between EEG and behavior, there is growing evidence that the pattern of EEG asymmetry and its relationship to affect and behavior vary as a function of gender in both children (Baving, Laucht, & Schmidt, 1999, 2002; Henderson et al., 2001) and adults (e.g., Kline, Allen, & Schwartz, 1998; Kline, Blackhart, & Schwartz, 1999). These findings are joined by gender-linked differences in raw EEG patterns among depressed individuals (Armitage et al., 2000; Armitage, Hudson, Trivedi, & Rush, 1995). This underscores studies indicating that Major Depressive Disorder is twice as prevalent in adolescent and adult females as in their male counterparts (Angold, Erklani, Silberg, Eaves, & Costello, 2002; American Psychiatric Association, 1994) and suggests that measures of EEG asymmetry may reflect the differential mechanisms at play.

Taken together, the adult and developmental data indicate that EEG asymmetry may reflect stable individual differences in temperament and motivation that are early appearing and may endure into adulthood. Resting frontal EEG asymmetry may reflect the valence of the motivational or affective bias, and the absolute power of the EEG

signal may reflect the intensity of the affective experience (Schmidt & Fox, 1999).

Measures of electrocortical activity have proven to be extremely useful in developmental psychopathology. The technology is noninvasive, relatively easy to employ, and amenable to use across a wide age spectrum. As a result, researchers have available to them a set of interrelated, but distinct, measures to address questions of trait-level differences in functioning and motivation as well as changes that occur in response to change in the environment.

Affective Modulation of the Startle Reflex

The startle reflex is a defensive response, and hence, theoretically, should be enhanced when an organism is presented with an aversive or threatening stimulus. This is the basis for research that uses the startle paradigm to explore emotional reactivity. According to P. J. Lang (1995, p. 372), "Defensive reflexes, including startle, increase in amplitude when an organism is aversively motivated . . . [and] . . . defensive reflexes are reduced in amplitude when an organism is positively motivated." It is not within the scope of the current work to provide a depth of knowledge into the nature and the neural circuitry involved in such appetitive and aversive motivational systems (see P. J. Lang, 1995, for a full review). However, there is considerable evidence to support this claim, as Davis and colleagues (M. Davis, Hitchcock, & Rosen, 1987) have documented that the neural circuitry involved in conditioned fear is the same as that involved in fear-conditioned startle potentiation. Two neural circuits are believed to be responsible for fear-potentiated startle in rats. The first is the primary brain stem pathway, which transfers auditory input to the reflex effectors vis-à-vis the reticular formation. The second path mitigates transmissions in the primary circuit, as projections from the central nucleus of the amygdala to the reticular locus of the primary pathway described earlier. Davis and his colleagues have shown that the primary neural circuit attenuates or ameliorates startle responses. Additionally, lesions of the amygdala have been found to eradicate the startle response (Boulis & Davis, 1989; Hitchcock & Davis, 1986; Rosen & Davis, 1988).

According to M. M. Bradley, Cuthbert, and Lang (1999), affective modulation of the startle reflex is a robust method for measuring the activation of the underlying appetitive and aversive, or approach-withdrawal, systems, particularly because it captures the state of the organism prior to the onset of fight/flight behavior. The startle reflex itself is an index of the preparatory state of the organism

prior to initiation of the flight response, which is consistent with literature that has found fear-induced freezing in rodents to be associated with startle potentiation; no such relationship exists when the animal is in an active state or responding to aversive stimuli. For instance, Grillon, Ameli, Woods, Marikangas, and Davis (1991) showed that the startle reflex is consistently potentiated in humans when the experimental condition involves a verbally instructed threat. Essentially, once the flight component of the fight/flight system is engaged, startle potentiation is no longer a useful measure of emotional reactivity, as affective startle modulation will be eradicated once the organism has become overtly reactive. In short, potentiation of the startle reflex during presentation of affectively negative stimuli is an early indicator that the organism has detected a threat; as such, it is an index of the activation of the appetitive/aversive motivational systems.

Affective Modulation of Startle Methodology

The methods of data collection for the startle paradigm were previously discussed in this chapter (see discussion of prepulse inhibition). The setup and collection of data in studies that seek to explore affective modulation are identical in terms of lead placement and outcome measure (magnitude of the blink reflex following a startling probe). However, whereas studies of prepulse inhibition involve manipulation of the timing of the lead interval of a nonstartling, benign, prepulse stimulus, the paradigm to assess affective modulation involves manipulating the affective state of the subject prior to or during presentation of the startle probe.

Lang and his colleagues have explored the affective modulation of the startle reflex for well over a decade and have provided empirical support for the notion that the amplitude of the startle reflex varies systematically based on the ongoing emotional valence of individuals. Using a sample of undergraduates, Vrana, Spence, and Lang (1988) showed that acoustic startle probes were augmented during the presentation of negatively valenced slides, which included photographic stimuli of such unpleasant images as starving children, angry human faces, violent death scenes, and an aimed gun. In contrast, when undergraduates viewed positively valenced pictures such as those depicting happy babies, attractive nudes, and chocolate, startle responses to acoustic probes were attenuated. A later study (M. M. Bradley, Cuthbert, & Lang, 1990) extended this early work by demonstrating a linear relationship between the degree of emotional arousal participants reported while viewing foreground stimuli and startle potentiation, beyond the potential effects of startle probe modality (i.e., acoustic versus visual) and participant self-

reported interest in the foreground stimuli. Another study by this research group (Cuthbert et al., 1996) showed that the affective modulation of startle potentiation is linearly related to the degree of arousal of the foreground stimuli, such that blink potentiation in the presence of negative stimuli and blink inhibition in the case of positive stimuli were most pronounced when participants reported that the corresponding stimuli elicited high degrees of arousal.

Affective Modulation of Startle and Developmental Psychopathology

The developmental literature on the role of startle modulation in both normative and abnormal processes is still in its infancy. Indeed, very few published studies have examined the role of affective modulation of startle in infants or children, and the little work that has been done has yielded mixed findings. In her study of 5-month-old infants, Balaban (1995) found early evidence for the emergence of the adult affectively modulated startle responsiveness. Specifically, infants showed startle potentiation while viewing pictures of happy faces and attenuated eyeblink magnitude while viewing photos of angry faces. In contrast are two known studies that sought to replicate this pattern in older children. McManis, Bradley, Cuthbert, and Lang (1995) examined affective startle modulation in children ages 7 to 10 and found no evidence of a generalized adult-like response pattern, although further analyses revealed that girls showed the typical affectively modulated pattern but boys did not. Similarly, Cook, Hawk, Hawk, and Hummer (1995) found no evidence of the affective modulation of startle in their school-age sample. Given only the infant evidence, it could be concluded that affective modulation of the startle reflex is salient in the early months of life. However, Cook et al. and McManis et al. show no evidence for the phenomenon in middle childhood. As pointed out by Ornitz (1999), there is much yet to be learned about the normal development of affective modulation of startle. Certainly, three studies alone do not provide sufficient resolution to this issue. For instance, one plausible explanation forwarded by Ornitz for the infant findings in light of the null findings for the same effect in older samples is that the infant pattern of responding is due to attentional focus, in that angry faces perhaps mark a more novel, and therefore interesting, set of stimuli to infants than neutral or happy faces.

Given the general scarcity of findings of affective modulation of startle in children, normal or atypical, one must turn to the adult literature to consider the contribution and relevance of the paradigm to issues related to developmental psychopathology. The degree of affective modulation in the startle response has been examined in studies of

psychopaths (Patrick, Bradley, & Lang, 1993) and fearful (Cook, Hawk, Davis, & Stevenson, 1991) and clinically depressed (Allen, Trinder, & Brennen, 1999) adults and in anxiety disorders, including PTSD (Morgan, Grillon, Southwick, Davis, & Charney, 1995) and specific phobia (Hamm, Cuthbert, Globisch, & Vaitl, 1997; Vrana, Constantine, & Westman, 1992).

Perhaps the best evidence for the contribution of the startle paradigm to the study of abnormal psychological development comes from the literature investigating the affective modulation of startle response in criminals and psychopaths (Patrick, 1994; Patrick et al., 1993). By definition, psychopathic individuals show marked abnormalities in affective responsiveness. According to Cleckley's (1976) criteria, individuals with primary psychopathy manifest antisocial behaviors due to an underlying deficit in emotional processing. Lykken's (1957) landmark study revealed that, relative to normal controls, psychopathic adults showed less anxiety on measures of self-report, less galvanic skin response reactivity to a conditioned shock, and less avoidance of punishment during a test of avoidance learning. This work provided the earliest evidence that the primary deficit in psychopaths involves a lack of anxiety. The predominant theory of psychopathy still contends that the central deficit in individuals who meet the criteria for true psychopathy is a lack of behavioral inhibition in response to punishment or nonreward (Fowles, 1980; Patrick, 1994).

According to Patrick (1994), the literature offering evidence for a lack of fear in psychopathic samples is limited by the use of autonomic indices, which confound assessments of the behavioral inhibition system with more generalized sympathetic arousal and higher-level processing. Further, although autonomic measures such as electrodermal activity should, theoretically, increase with activation of the behavioral inhibition system (Fowles, 1980), empirical support for this claim in normative samples does not abound (e.g., see Fowles, Kochanska, & Murray, 2000; Keltikangas-Järvinen, Kettunen, Ravaja, & Näätänen, 1999). Hence, autonomic measures fail to provide satisfactory evidence for Lykken's (1957) and Cleckley's (1976) notions regarding the affective deficit involved in psychopathy.

Patrick and his colleagues (1993) used startle methodology and autonomic measures to examine affective processing of psychopathic and nonpsychopathic men among a population of incarcerated sex offenders. They examined the degree of startle potentiation during the presentation of emotionally pleasant, unpleasant, or neutral pictures. Results showed that there were no statistically significant differences between incarcerated, nonpsychopathic men and a control sample of college students. In other words, for these

two groups, startle responses were appropriately inhibited during presentation of positive stimuli and potentiated during presentation of negative stimuli.

In stark contrast was the psychopathic group, who not only failed to show startle potentiation during the presentation of the negatively valenced photos, but instead showed an inhibition in their blink amplitude relative to neutral slides. Hence, the psychopathic group manifested startle inhibition during presentation of both positively *and* negatively valenced stimuli, providing profound evidence that the nature of emotional processing between these two groups is quite discrepant. An additional subgroup of men in the study who were classified as "mixed" fell between the cutoff for clinical diagnosis of psychopathy but scored higher than average on the index of psychopathy used in this study. When this subgroup was added to the group of psychopaths, a correlation was found between degree of emotional detachment and startle potentiation to negative stimuli, such that individuals who were the most emotionally detached showed the highest levels of startle inhibition during presentation of negative stimuli (or the reversed startle potentiation effect). No between-group differences were found for autonomic response patterns: All participants showed increases in skin conductance reactions to both positive *and* negative stimuli and all showed normal patterns of heart rate deceleration.

Future Directions in the Use of Affective Startle

The application of the startle paradigm to the study of psychopathy by Patrick and his colleagues (1993) has yielded important contributions that would not have been obtained via the use of other psychophysiological measures. We suggest that startle methodology holds great promise for the early assessment of psychological risk. Methodologically, data collection is relatively clear-cut and lends itself to work with young children and infants. The ability to tap "pure" responses directly based on the neural circuitry involved in the processing of fear and pleasure (Ornitz, 1999) makes interpretation of startle data quite clean.

One logical extension of the current work in affective startle is to attempt to replicate the findings of Patrick and his colleagues (1993) in samples of children and/or adolescents. For instance, an examination of affective startle responses in a clinical sample of conduct disordered boys is currently under way in our laboratory. This work will extend the work of Patrick and his colleagues in psychopathy by establishing the degree to which the physiologically based absence of fear manifest by adult criminal samples is evident among the group of children who are at greatest risk for subsequent development of the adult condition.

One study by Schmidt and Fox (1999) also demonstrates the benefits of using the startle methodology to assess degree of risk for deviant development. Schmidt and Fox found amplified fear-potentiated startle in a subgroup of negatively reactive 9-month-olds at risk for behavioral inhibition in childhood, which can act as a precursor to anxiety disorders in childhood. This increase in startle amplitude was specific to a laboratory stranger approach paradigm, as no differences in baseline startle were found. This work provides evidence that amplified startle responses may be used as an index of early risk for the subsequent development of anxiety-related conditions.

In short, although the developmental literature in affective modulation of startle is far from sufficient, adult studies such as those of Patrick and his colleagues (Patrick, 1994; Patrick et al., 1993) and infant work by Schmidt and Fox (1999) illustrate the potential benefits of applying the measure to young samples who are at risk for the development of conditions associated with the processing of fear, be it increased or deficient fear-related reactivity. Of particular importance, following such children who have manifested early behavioral and physiological risk across childhood and adolescence will enable researchers to explore the degree to which environmental factors alter the developmental trajectories of children marked by physiologically substantiated risk.

CONCLUSIONS AND FUTURE DIRECTIONS

Unlike many chronic diseases, psychopathology, in the form of either the diagnosable disorder or its developmental precursors, is often evident early in life (Giaconia, Reinherz, Silverman, & Pakiz, 1994; Institute of Medicine, 1989; World Health Organization, 2000). This early appearance is a vital component of attempts to both treat and prevent psychopathology in the population. This is in line with Kohlberg, LaCrosse, and Ricks's (1972, p. 217) view that the ability to predict outcome is the "single most important area of study of clinical theory and practice with children." Yet, although researchers and clinicians are skilled at describing and categorizing these early phenotypes, their larger work is hampered by the fact that the phenotypes are only moderately predictive of later psychopathology (Kagan, 1994).

In addressing these concerns, Sroufe and Rutter (1984) have made the distinction between developmental coherence and developmental stability. That is, although psychologists

have found very few traits or abilities that remain truly stable over time, the course of an individual's development is both lawful and coherent in nature. They argue that continuity lies not in the presence of a specific behavior across time, but in the lawful relationship between early and later behavior, even if the link is exceedingly complex. This is true in the case of both normative and atypical development (Cicchetti & Sroufe, 1978). This view of development as a dynamic yet lawful progression suggests that researchers must rely on multiple measures, collected over time, to describe and assess the relationships among the components within the person-biology-experience structure. These multiple measures are then used to assess multiple components of the observed outcomes. These include the factors, processes, and mechanisms involved in producing both typical and atypical development (Garmezy, 1996).

In looking for the antecedents of later psychopathology, researchers familiar with the adult presentation of a disorder may begin their study of children by trying to find phenotypically similar behaviors in the young. For example, does the 7-year-old bipolar child behave similarly to the 27-year-old bipolar adult (Biederman et al., 2003; Tillman & Geller, 2003)? The same is true for high-risk studies in which risk is linked to one proscribed outcome. Erlenmeyer-Kimling (1996) points out that many Schizophrenia studies predicted that their participants would either be "manifestly schizophrenic or clinically unremarkable." Instead, the data indicate that children at risk for a specific disorder can display their vulnerability in a wide variety of behaviors. These findings reinforce Sroufe and Rutter's (1984) suggestion that researchers may do better in deemphasizing phenotypic mirrors throughout development and instead focus on failures in adaptation, which are defined through core developmental issues.

As the preceding discussion makes clear, psychophysiological measures are ideal for this work. Varying in the systems of interest, the time course of measures, and the psychological constructs addressed, psychophysiological measures, particularly when used in combination, can provide an additional window onto the psychological mechanisms underlying both risk and resilience in early development. The flexibility found in psychophysiology allows researchers to address some of the core questions surrounding developmental psychopathology. To illustrate, we can use Keller et al.'s (2000) summary of important questions that the field of developmental psychopathology should address.

First, what are the psychological and physiological causes of the psychophysiological differences? Systematic

use of psychophysiological measures that are anatomically and functionally well-defined, like the startle response, in conjunction with traditional behavioral measures, will help target the root forces underlying observed differences. Second, at what stage of processing do individuals with psychopathology begin to diverge from controls? This question can be answered at the micro level across the span of milliseconds, as seen in the ERP, or at the level of the relatively laconic LHPA system. Third, under what conditions are individuals with psychopathology able to mimic controls in their performance of mental operations? This question is analogous to studies attempting to examine the conditions under which children display adult-like performance on a task. Psychophysiological measures allow researchers to address this question across a number of domains, from cognition to motivation and emotion. Fourth, do the processing differences seen within or across diagnostic groups reflect a deficit or a compensatory tactic? This question is of particular interest when comparisons between psychophysiological and behavioral data show a dissociation in findings. If, for example, two groups of children display identical behavioral outcomes in a task but diverging psychophysiological functioning, one may then begin to explore the possibility that the groups are using different strategies or processes to achieve the presented goal.

In addition to Keller et al.'s (2000) questions, psychophysiology can also help address two interrelated issues of central importance in developmental psychopathology: differential diagnosis and comorbidity. To date, *Diagnostic and Statistical Manual of Mental Disorders* diagnostic categories are almost exclusively reliant on observed behavior coupled with self- or parent report (American Psychiatric Association, 1994). However, as our understanding of the biological substrates of behavior grows, it may be wise to incorporate psychophysiological measures into the diagnostic process. The early work in this process can be illustrated by recent research with ADHD. ADHD is a highly comorbid disorder often co-occurring with Conduct Disorder and Oppositional Defiant Disorder (Bird, Gould, & Staghezza-Jaramillo, 1994), anxiety disorders (August, Realmuto, MacDonald, & Nugent, 1996), depression (Woolston et al., 1989), and learning difficulties (August & Garfinkel, 1990). For example, 40% to 70% of children with ADHD are also diagnosed with either ODD or CD (Banaschewski et al., 2003), and these children tend to exhibit more psychosocial difficulties than their counterparts who also have ADHD but show no co-occurring psychopathology (Kuhne, Schacher, & Tannock, 1997).

Recent work has attempted to aid diagnosis and classification through the use of psychophysiological measures. For example, Mann et al. (Mann, Lubar, Zimmerman, Miller, & Muenchen, 1992) found that EEG measures incorporated into a discriminant function analysis could accurately predict group membership 80% of the time. Chabot and Serfontein (1996) found that a similar analysis using nine EEG variables had a correct classification rate of 95% and 93% for ADHD and non-ADHD children, respectively. Clarke and colleagues (Clarke, Barry, McCarthy, & Selikowitz, 2001b) used EEG-based cluster analyses to create three distinct subtypes within their sample of boys with ADHD. In a related vein, Banaschewski et al. (2003) have used ERP component differences to argue that ADHD comorbid with Conduct Disorder constitutes a "separate psychopathological entity" from ADHD in its pure form.

With the addition of new sources of information, particularly if they bring information from a different level of functioning, we may better define the boundaries and characteristics of our target population (Kagan, 1996). This allows the researcher to reduce the amount of heterogeneity within a group or even create subgroupings (Cicchetti & Rogosch, 1996; Richters, 1997). In this way, research can continue with greater precision, parsing out the multiple pathways to and manifestations of an underlying maladaptation. From a historical perspective, the addition of new technology, coupled with rigorous methodology, has moved the study of pathology in childhood from the nineteenth century's reliance on "degeneracy" as the broad-brush answer to maladaptation (S. H. White, 1996) to the current complex, and perhaps confusing, network of explanatory mechanisms.

Further complicating our understanding of deviant processes underlying pathological states is the dynamic nature of the system itself. Although the use of psychophysiological indices provides a window onto the biology underlying behavior, these measures are not impervious to contextual forces. Indeed, the transactional model set forth by Sameroff and Chandler (1975), which emphasized dynamic relationships between the child and his or her environment across time, is quite meaningfully applied to studies of psychophysiology, as physiological mechanisms reorganize in response to environmental demands (Campos et al., 1989). Our model of neuroplasticity holds that behavioral change is the result of a complex series of transactions between genetic programs that direct the formation and connectivity of brain structures and environmental modifiers of these codes (N. A. Fox, Calkins, & Bell, 1994). An emergent

body of literature supports this notion, as changes in physiology based on environmental circumstances have been documented in humans (N. A. Fox et al., 2001) and nonhuman primates (Bennett et al., 2002). Curtis and Cicchetti (2003, p. 803) have indicated that “the incorporation of a biological perspective into research on resilience still requires adherence to a dynamic, transactional view that respects the importance of context.”

Given such evidence, it is clear that the field of physiology will make a significant contribution to the study of psychopathology only by rising to the challenges posed by the transactional model of development. One way to do this is by studying children early—an option nicely accommodated with the use of psychophysiological measures. Groups found to be at risk behaviorally and/or physiologically should then be followed at critical junctures of development and reevaluated not only behaviorally or psychophysiological but also in terms of the presence or absence of environmental stressors. Indeed, Sameroff and MacKenzie (2003) caution that the success of such models hinges on the outlining of a careful schedule of assessments that target the developmental periods when the environment and the child are most likely to be altered by each other (and hence most likely to change).

It is because of the bidirectional environment-physiology relationship that developmental psychophysiology holds great promise for the study of developmental psychopathology, as psychophysiological measures allow for the quantification of proximal influences at the most basic biological level. However, our greatest potential for contribution may also be our downfall, as research attempts that fail to monitor the degree of change in physiology in accordance with the presence or absence of relevant ecological influences will lead to short-sighted, overly simplistic conclusions. Research programs that adhere to transactionally oriented designs will likely be the most profitable in advancing current understanding regarding the antecedents and consequences of normative and aberrant development. Indeed, measures of psychophysiology reflect only one dimension of an intricate ensemble of systems, individual and contextual, which together alter the course of development.

FUTURE DIRECTIONS	454
REFERENCES	457

Although the perception of behavioral genetic research by developmentalists has undergone a number of transformations over the past few decades (ranging from resistance to widespread acceptance), the fundamental purpose of elucidating and understanding both genetic and environmental contributions to behavioral development (both adaptive and maladaptive) has not wavered in importance or effort. As indicated in the title of this chapter, the most notable advancement in the field over the past decade has been the expansion of traditional behavioral genetic research (e.g., twin, family, and adoption studies) to include state-of-the-art molecular genetic approaches. Indeed, it may be argued

that behavioral genetics, both as an empirical enterprise and as a theoretical orientation, has forcefully shaped the direction of the conceptual and methodological approaches that are currently being applied to understanding the etiological architecture of psychopathology (Rende, 2004). Of particular note is the emphasis on both genetic and non-genetic contributions to etiology, including overt attention to a number of mechanisms by which genes and environment interrelate.

This chapter examines advancements in the field that have been influenced by and/or have implications for developmental psychopathology. As discussed in detail in the first edition to these volumes (Rende & Plomin, 1995), developmental psychopathology and behavioral and molecular genetics have many avenues for fruitful overlap. For example, core issues in developmental psychopathology, such as the delineation between normative and maladaptive—the “distinction” between the normal and

This work was supported by a number of grants funded by the National Institutes of Health, including MH001559, MH062989, DA016795, CA0841719, and MH001818. We thank Dante Cicchetti for many good suggestions for improving the content of this chapter.

abnormal—are particularly rich topics for behavioral genetic methodologies as well as molecular strategies. Similarly, themes that have been prominent for decades in behavioral genetics, such as the developmental interplay between genetic and environmental influence, are quite consistent with the systemic and interdisciplinary foundation of developmental psychopathology and are beginning to take on new meaning with the inclusion of molecular genetic techniques.

With this natural and fruitful merger between developmental psychopathology and behavioral and molecular genetics in mind, this chapter is organized around four core topics: theoretical and methodological foundations of behavioral genetics, advances in behavioral genetics and developmental psychopathology, molecular genetic approaches to developmental psychopathology, and future directions. Our goal is to illuminate critical themes that have emerged over the past decade that have shaped current thinking and hold promise for yielding future insights into our understanding of the development of psychopathology. Furthermore, we emphasize that for the purposes of this chapter, we are drawing a distinction between behavioral genetics and molecular genetics. This heuristic is organizational and allows us an opportunity to discuss in turn the yield of traditional behavioral genetic approaches that utilize natural experiments (i.e., genetically informative designs) as well as the newer enterprise of examining DNA (and environments) in relation to behavioral development. In principle, these two domains represent complementary and mutually informative strategies for studying the complex mix of genes and environment in a developmentally sensitive framework aimed at elucidating mechanisms that either promote or buffer against psychopathology.

THEORETICAL AND METHODOLOGICAL FOUNDATIONS OF BEHAVIORAL GENETICS

Prior to reviewing the many advances that have occurred in behavioral and molecular genetics, it is worthwhile to highlight the theory that not only provides a foundation for behavioral genetic research but also unifies current thinking in behavioral and molecular genetics. (Table 10.1 presents definitions for key terms in this section on behavior genetics.) For many decades, behavioral genetics has relied on quantitative genetic theory, which is a framework for understanding individual differences on a trait (continuous or categorical) in a population. Quantitative genetic theory postulates that individual differences (or variation) on a phenotype may be attributed to both genetic and nongenetic

TABLE 10.1 A Glossary of Terms for Behavioral Genetics

Term	Definition
Additive genetic effects	Genetic effects on individual differences on a trait or disorder that statistically add up to produce variation in the population.
Adoption design	A class of natural experiments that utilize a disentangling of genetic relatedness and rearing environment.
Gene \times Environment correlation	Genetic effects that contribute to the level of an environmental variable.
Gene \times Environment interaction	Genetic effects on a trait or disorder that are dependent on the level of an environmental variable.
Genetically informative design	A class of natural experiments that provide manipulation of genetic relatedness and/or rearing environment.
Heritability	A descriptive statistic that assigns an effect size to the genetic contribution to a trait or disorder that is attributable to inheritance.
Knock-out gene studies	Studies in model organisms, such as mice, in which one or both copies of a gene are deactivated and the effects on behavior and/or cognition are examined.
Liability	A theoretical construct in quantitative genetic theory that reflects the underlying effects of genes on a multifactorial disorder.
Multifactorial	Quantitative genetic model that incorporates the net effect of multiple genetic and environmental influences on a trait.
Nonshared environment	A descriptive statistic that assigns an effect size to the portion of unexplained variance on a trait or disorder.
Polygenic	Genetic influences that reflect effects of multiple genes on a trait.
Shared environment	A descriptive statistic that assigns an effect size to nongenetic or environmental influences on a trait or disorder that promote similarity among individuals reared together.
Twin design	A natural experiment that compares the similarity of monozygotic (MZ) and dizygotic (DZ) twins.
Zygoty	An indicator of genetic relatedness based on an additive genetic model.

influences. One key feature of the theory is that genetic influences reflect the impact of a number of genes rather than one gene, and as such, the theory relies on polygenic influence. It is postulated that a combined effect of such genes contributes to the manifestation of individual differences on a trait (or variation in the population on that trait). The fundamental quantitative genetic model assumes that this combined effect is additive, such that variation in each gene contributes (or adds up) to shape phenotypic variation. Alternative nonadditive effects (such as dominance) are possible and can be accommodated in the model. A sim-

ilar perspective applies to nongenetic (or environmental) influence in quantitative genetic theory, as it is typically assumed that a number of environmental influences may also have an additive effect in producing phenotypic variation in the population. Finally, the model assumes error or nonexplained influences on phenotypic variation. Thus, the fundamental model is multifactorial (in that it assumes an unspecified number of both genetic and nongenetic influences) and polygenic (by assuming that a number of genes impact the manifestation of the phenotype).

Quantitative genetic theory has been utilized for decades in behavioral genetics by the application of genetically informative designs, which typically are natural experiments that provide some manipulation of genetic and nongenetic factors. The most commonly used paradigm is the twin method, which was formally proposed in the 1920s (Rende, Plomin, & Vandenberg, 1990), when there was clear recognition that there are two types of twins, monozygotic (MZ) and dizygotic (DZ). MZ twins share 100% of their genes and are thus also referred to as identical twins. DZ twins are, from a genetic perspective, biological siblings who are the same age and are thus also referred to as fraternal twins. The classic twin paradigm capitalizes on this natural experiment by comparing the similarity of MZ and DZ twins; if MZ twins are more similar on a trait than DZ twins, then heritability is assumed to be important for that trait and responsible for the difference in twin similarity. This inference is dependent in part on the equal environments assumption, which states that the rearing environment of MZ and DZ twins does not differ and thus differences in twin similarity are attributable to heritable factors and not environmental influences.

A powerful design is the adoption paradigm, which refers to a variety of methods that utilize both adoptive and nonadoptive (or biological) family members. The fundamental principle underlying the information yield of adoption studies is the cleaving of biological parentage and social rearing environment. One comparison examines the similarity of biological parents and their offspring that were adopted, typically very early in life, as an index of genetic contributions to a trait. The similarity between adoptive parents and their adopted offspring provides a direct measure of environmental influence, assuming that there is no selective placement (matching of adoptive parent traits to biological parent traits). Other adoption designs include comparisons of biological and adoptive siblings. Given the clear distinction between biological parentage and social environment in the adoption design, there are also opportunities to examine the interplay of genes and environment (e.g., the genetic contribution of the biological parent[s]

crossed by the environmental influence of the adoptive parents), including gene-environment interaction and gene-environment correlation.

Research over the past decade has also capitalized on other natural experiments. The combined twin-sibling design expands the classical twin paradigm to include other sibling types of varying genetic similarity, including full biological siblings, half-siblings, and unrelated siblings. This paradigm is useful in that it combines features of both the twin and adoption paradigms and allows an integrated picture of sibling similarity as a function of a broad range of biological relatedness, or zygosity. A combination of the twin and adoption study methodology yields comparisons of twins reared apart and twins reared together, a more rare but nonetheless highly informative design. As discussed later in this chapter, there is current interest in the children of twins design, which examines the offspring of MZ and DZ twins.

All of these designs have one commonality: a naturally existing differentiation (either in level of genetic relatedness or in genetic versus social parentage) that can be modeled to yield information on both genetic and environmental contributions to individual differences on a trait. As discussed in the first edition to these volumes, a major advance in behavioral genetics was the development of biometrical model fitting, or the application of systematic analytic models that could test the fit of alternative models combining the effects of genes and environment. Biometrical models are used to quantify the statistical effect size of both genetic and environmental influence. Genetic effects are captured by the construct of *heritability*, which is a descriptive statistic that assigns an effect size to genetic influence. Environmental influences that promote similarity among family members are captured by the descriptive statistic *shared environment* (or common environment). Nonfamilial resemblance (including error of measurement) is indicated by the descriptive statistic *nonshared environment*. Most behavioral genetic studies utilize a genetically informative design and biometrical models to provide parameter estimates of these three basic descriptive statistics. It should be noted that these three descriptive statistics correspond to the basic theoretical constructs proposed by quantitative genetic theory, as described earlier. Also, as discussed later in this chapter, these descriptive statistics are often calculated for a theoretical construct of liability to psychopathology when the outcome measure of interest is a diagnosed disorder.

Before turning to the behavioral genetic literature, two considerations must be emphasized. First, as described earlier, genetically informative designs are natural

experiments and must be recognized as having the limitations inherent in any nonexperimental approach to behavior. Second, given that the constructs of heritability, shared environment, and nonshared environment are descriptive statistics, they are specific to the population studied as well as the methods used to study that population. Thus, these indicators may and do change across studies, environmental contexts, age, and generation. Indeed, some of the major advances in behavioral genetics have come from explicitly modeling how these descriptive statistics change based on these considerations. We now turn to the vast yield of behavioral genetic studies with particular relevance for developmental psychopathologists.

ADVANCES IN BEHAVIORAL GENETICS AND DEVELOPMENTAL PSYCHOPATHOLOGY

Traditional behavioral genetic research has continued at a rapid pace with an extraordinary number of high-quality papers represented in journals. Much of the work over the past decade has relied on the benchmark twin paradigm, although, as discussed later, other alternative and complementary designs have also been utilized. As has been the case with behavioral genetic research over the past few decades, many studies have gone beyond the “simplistic” delineation of heritable and nonheritable influences to address themes of fundamental importance to developmental psychopathology. In this section, we highlight four such themes that have been prominent over the past decade: (1) construction of developmental models of psychopathology, (2) use of genetically informative designs to understand environmental contributions to psychopathology, (3) use of genetically informative designs to hone in on the heritable contributions to psychopathology, and (4) advancement in methods that have potential for improving the yield of information for developmental psychopathology.

Developmental Models of Psychopathology

Behavioral genetic research has often involved developmentally informative designs, including both cross-sectional and longitudinal studies. The fruit of these labors is becoming more clear as empirically supported models of the development of various forms of psychopathology are emerging. Perhaps the clearest examples of how behavioral genetic studies have yielded potentially useful developmental models have come from research on substance use,

especially research on tobacco and alcohol use. We begin this section with a focus on tobacco use and then progress through other domains that have been studied.

Since a landmark paper by Carmelli, Swan, Robinette, and Fabsitz (1992) provided evidence for the heritability of smoking using the classic twin method, there have been a number of twin studies focused on varying levels of smoking intensity, ranging from initiation to smoking persistence to dependence. As discussed in reviews by Sullivan and Kendler (1999) and Li, Cheng, Ma, and Swan (2003), both genetic and shared environmental factors (i.e., environmental factors that operate to produce similarity in family members) are implicated for all of these indicators of smoking behavior, but the relative mix appears to be different for different levels of smoking intensity. For example, using meta-analysis, Li et al. (2003) have determined that smoking initiation is influenced significantly both by genetic factors (with heritability estimates of .37 for males, and .55 for females) and by shared environmental factors (.49 for males, and .24 for females). Li et al. also provide evidence of substantial heritability of smoking persistence (.59 for males and .46 for females), with shared environmental influences being more prominent for females (.28) than for males (.08). Sullivan and Kendler (1999) reached somewhat similar conclusions, suggesting substantial heritability of smoking initiation (approximately .60) along with significant shared environmental influences (approximately .20), with genetic factors being primarily responsible (heritability of approximately .70) for the transition to nicotine dependence and less impact observed for shared environmental influences.

It is of particular note that both Li et al. (2003) and Sullivan and Kendler (1999) emphasize the importance of shared environmental factors as well as genes on smoking initiation, which typically occurs during adolescence. Although there have been fewer behavioral genetic studies of adolescent tobacco use, compared to the number of reports on adults (Maes et al., 1999; McGue, Elkins, & Iacono, 2000), the studies to date have yielded intriguing results. First, there is strong evidence for shared environmental influences on smoking (Boomsma, Koopsman, van Doornen, & Orlebeke, 1994; Han, McGue, & Iacono, 1999; Koopsman, van Doornen, & Boomsma, 1997; Koopsman, Slutske, Heath, Neale, & Boomsma, 1999; McGue et al., 2000; Rende, Slomkowski, McCaffery, Lloyd-Richardson, & Niaura, 2005; Slomkowski, Rende, Novak, Lloyd-Richardson, & Niaura 2005; Vink, Willemssen, & Boomsma, 2003; White, Hopper, Wearing, & Hill, 2003), suggesting that there are etiological factors that

promote twin resemblance independent of genetic relatedness and thus are thought to represent social effects. Most typically, shared environmental effects have been most prominent for either initiation of smoking or an index of "ever smoking" (i.e., without taking into account intensity of smoking), leading to claims that environmental influences on initial experiences with cigarettes are critical (McGue et al., 2000) and perhaps even more influential than genetic contributions (Stallings, Hewitt, Beresford, Heath, & Eaves, 1999; White et al., 2003).

The results of a number of studies suggest that the progression from smoking initiation to higher levels of smoking intensity (e.g., persistence, regular use, nicotine dependence) depend in part on the activation of gene systems not implicated in initial exposure to cigarettes. For example, some longitudinal studies have suggested that progression from initial use to regular use reflects in part the expression of genetic susceptibility with little contribution from social influences (Boomsma et al., 1994; Koopsman et al., 1997, 1999). Although there is some evidence of overlap between the genetic contributions to initiation and either persistence or dependence, a number of studies that have utilized multivariate models have reported that there are genetic influences unique to these higher levels of smoking intensity. Kendler et al. (1999) have proposed unique genetic influences (i.e., separable from those that influence smoking initiation) for nicotine dependence; Madden et al. (1999; Madden, Pedersen, Kaprio, Koskenvuo, & Martin, 2004) and Heath, Martin, Lynskey, Todorov, and Madden (2002) have shown that smoking persistence involves genetic contributions that are separable from those found for smoking initiation.

Taken together, a number of behavioral genetic studies, both cross-sectional and longitudinal, and representing informative samples taken from a variety of cultures, support the notion that shared experiences between family members (i.e., the shared environment) is a critical risk factor that increases risk for initiating smoking in adolescence. These same studies also support the notion that genes contribute to this risk, and that these genes influence in part progression to higher levels of smoking intensity. However, there is support for the contention that a unique set of genetic factors are activated by exposure to tobacco and influence progression to smoking persistence and nicotine dependence. This straightforward developmental model is not only well supported empirically, but offers an intuitive appeal (social factors promote risky behavior, whereas biological factors become most prominent in terms of responsivity to exposure to a substance). One fundamental implication for develop-

mental psychopathology is the potential utility to consider environmental factors (especially those that are shared by family members) as targets for prevention and intervention models aimed at reducing the likelihood of smoking initiation in adolescence (e.g., McGue et al., 2000). A complementary implication is that attention to genetic and biological factors will be critical for understanding individual differences in responsivity to tobacco exposure (Swan et al., 2003). Of note here is the possibility that such genetic sensitivity may be apparent even in adolescence as both high frequency of smoking and symptoms of dependence have a heritable component (McGue et al., 2000; Rende et al., 2005). Thus, although the typical trajectory of influences may involve social (and genetic) effects on initiation in adolescence and later contributions of genes to persistence and dependence in adulthood, it may be that the developmental trajectory may be much more rapid in some youth, perhaps especially those at high genetic risk.

This fundamental developmental model that emphasizes environmental contributions to exposure and genetic foundations for sensitivity once exposed appears to hold promise for substances other than tobacco. A number of twin studies of alcohol use in adolescence report robust shared environmental effects (Buster & Rogers, 2000; Cleveland & Wiebe, 2003; McGue, Iacono, Legrand, & Elkins, 2001; Rose, Dick, Viken, & Kaprio, 2001; Viken, Kaprio, Koskenvuo, & Rose, 1999). Of particular interest from a developmental perspective is the distinction between initiation of drinking and engaging in heavier levels of use. Initiation of drinking in adolescence (i.e., comparing adolescents who have never had a drink to those who have) has been reported to be highly influenced by shared environmental effects (Rose, Dick, Viken, Pulkkinen, & Kaprio, 2001; Viken et al., 1999), whereas escalation to high levels of drinking (such as drinking to intoxication) appears to be less impacted by shared environmental influences but more indicative of genetic differences (Viken et al., 1999). Furthermore, a combined sibling/twin/adoption study of substance initiation, use, and problem use in adolescence has supported this general model for a number of substances, including tobacco, alcohol, and other drugs such as marijuana (Rhee et al., 2003). Expanding the findings discussed earlier for tobacco use, this study provided evidence that shared environmental factors contribute to initiation for alcohol, tobacco, and any drug use, and that heritability is more pronounced for problem use in adolescence than for initiation of any drug use. It may be suggested, then, that there is compelling evidence of a clear developmental model for substance use, with roles for shared environment and

genes in the etiology of exposure to and initial use of substances and potentially unique genetic factors specific to sensitivity to repeated exposure to the substances and hence progression of use. Again, although this model commences with initial exposure to substances in adolescence, the rate of progression to higher levels of use may also begin in adolescence and continue into adulthood.

Developmental models from a behavioral genetic perspective have begun to emerge for other domains of behavior. The theme of shared environmental influences exerting an impact prior to the activation of genetic effects has been prominent in research on depression. A fundamental difference from the work reviewed for substance use has been the developmental epochs of interest: Shared environment has been shown to affect depressive symptoms in childhood, with evidence that genetic effects become detectable in adolescence. For example, Rice et al. (2002), using cross-sectional analyses in a population-based sample of twins, have shown that shared environmental influences were prominent for children ages 8 to 10 years, whereas genetic factors were most influential for adolescents (ages 11 to 17). Further longitudinal analyses have confirmed this pattern detected from the cross-sectional study, with evidence for new genetic influences that emerge in adolescence (Scourfield et al., 2003). This line of work has also suggested that the activation of genetic influences in adolescence may be related to genetic correlation with experiencing negative life events (Rice, Harold, & Thapar, 2003). Silberg et al. (1999) have made a similar argument, presenting analyses derived from the Virginia Twin Study of Adolescent Behavioral Development supporting the notion that a set of genes common to both depression and life stress is activated in adolescence, particularly for girls once puberty is achieved.

From a developmental perspective, an additional intriguing idea is that there are links between anxiety in childhood and depression in adolescence. Studies of offspring of depressed parents have long supported the contention that familial risk for depression first manifests as anxiety in childhood, followed by depression in adolescence (Rende, Wickramaratne, Warner, & Weissman, 1995; Warner, Weissman, Mufson, & Wickramaratne, 1999) and adulthood (Rende, Warner, Wickramaratne, & Weissman, 1999). Behavioral genetic work posits two unique pathways underlying this association, as exemplified by work conducted by Silberg and coworkers (Silberg, Rutter, & Eaves, 2001; Silberg, Rutter, Neale, & Eaves, 2001). These authors provide evidence of genetic links between childhood anxiety (Overanxious Disorder and simple phobias) and depression in adolescence, as well as support

for (shared) environmental links between separation anxiety in childhood and depression in adolescence. Thus, these authors suggest that there may be etiologically distinct syndromes of depression, essentially one reflecting environmental effects and one more genetically driven.

From the genetic perspective, Eaves, Silberg, and Erkanli (2003) have presented a model arguing that the developmental pathway is complex and must take into account at least three streams of influence: direct genetic continuity between anxiety in childhood and depression in adolescence, gene-environment interaction (genes that contribute to early anxiety also confer sensitivity to life events that may manifest as depression), and gene-environment correlation (genes that contribute to early anxiety also increase likelihood of exposure to life events that influence depression). From the environmental perspective, the Silberg, Rutter, and Eaves (2001) and Silberg, Rutter, Neale, et al. (2001) emphasis on potential shared environmental influences on depression is consistent with research using DeFries-Fulker analysis, an analytic technique that examines the etiology of extreme scores in a distribution (Purcell & Sham, 2003; Rende & Slomkowski, in press). A number of studies using this method have shown that high levels of depressive symptoms in adolescence (e.g., symptom scores that are in a clinically significant range) are substantially influenced by shared environment, whereas individual differences in depressive symptoms are not (Deater-Deckard, Reiss, Hetherington, & Plomin, 1997; Eley, 1997; Rende, Plomin, Reiss, & Hetherington, 1993; Rice et al., 2002).

There is thus accumulating data and theory concerning developmental pathways to depression, including an emphasis on different developmental periods (childhood versus adulthood) as well as the possibility of etiological and phenotypic heterogeneity. This body of work is especially appealing in that it is hypothesis-generating and cuts across both high-risk studies of offspring of depressed parents (e.g., Rende et al., 1999) and twin studies (Silberg, Rutter, & Eaves, 2001; Silberg, Rutter, Neale, et al., 2001). Thus, the fundamental developmental association of anxiety in childhood and depression in adolescence may in fact represent two distinct pathways. First, there is the proposition that one form of depression onsets in childhood, as manifested by separation anxiety, with heterotypic continuity accounting for the expression of depression in adolescence, as mediated by shared environmental factors. A second proposition is that a more genetic form of depression, resulting from a common set of genes, includes expression of Overanxious Disorder and phobia in childhood and depression in adolescence, again

as a form of heterotypic continuity. What has not been broached from the behavioral genetic perspective is continuity into adulthood. There is little evidence of shared environmental influences on depression in adulthood, as most studies have shown only genetic effects (Sullivan et al., 2000). The one study to date of Major Depressive Disorder in adolescence has also provided evidence of genetic, but not shared environmental, influence (Glowinski, Madden, Bucholz, Lynskey, & Heath, 2003). Thus, it is clear that in the future, developmental models of depression will need to generate testable propositions concerning etiological influences that span from childhood into adulthood (e.g., Kendler, Gardner, & Prescott, 2002).

The theme of etiological heterogeneity has been prominent in developmental behavioral genetic studies of antisocial behavior. Retrospective reports gathered from adults have suggested that both genes and shared environment contribute to juvenile antisocial behavior (Jacobson, Prescott, & Kendler, 2000), with some evidence that a different set of genetic factors may operate in childhood versus adolescence and adulthood (Jacobson et al., 2000). It has been suggested that such unique genetic influence on childhood antisocial behavior reflects an increased heritability for early-onset delinquency (Taylor, Iacono, & McGue, 2000). An informative approach has been taken by Eley, Lichtenstein, and Moffitt (2003), as they incorporated two methodological features in a twin study: a longitudinal sampling frame (with measurement occurring at 8 to 9 years of age and again at 13 to 14 years of age) and a distinction between aggressive and nonaggressive antisocial behavior. These features allowed for the calculation of genetic and environmental influences at each time point for each subtype of antisocial behavior, as well as for the application of longitudinal behavioral genetic models aimed at understanding the etiology of continuity across time points. Eley et al. report that aggressive antisocial behavior was influenced primarily by genes in childhood, with genes and shared environment both contributing to adolescent antisocial behavior. Nonaggressive antisocial behavior was influenced by both genes and antisocial behavior in both childhood and adolescence. Perhaps most important, the continuity in aggressive antisocial behavior from childhood to adolescence was mediated primarily by genetic influences, suggesting that aggressive antisocial behavior is a stable heritable phenotype, in contrast to nonaggressive antisocial behavior, which was more strongly affected by the environment. Additional longitudinal studies, especially those that extend beyond adolescence and into adulthood, hold potential for shedding more light on the different developmental pathways leading

to subtypes of antisocial behavior. Of note in the Eley et al. approach is the emphasis on testing models that apply essentially not only to subtypes but to individual trajectories, an approach that has potential for understanding the etiology of complex phenotypes that undoubtedly reflect a number of heterogeneous behavioral types.

It is also worth noting that eating disorders—and related phenotypes such as eating attitudes and behaviors—have been examined using behavioral genetic approaches. A number of twin studies have demonstrated that eating disorders, especially bulimia nervosa, show evidence of substantial heritability and typically little evidence of shared environmental influence (Bulik, Sullivan, Wade, & Kendler, 2000; Bulik & Tozzi, 2004). There is also evidence that heritable influences are detectable for bulimic symptoms in adolescence (Rowe, Pickles, Simonoff, Bulik, & Silberg, 2002). Other types of eating behaviors also show evidence of significant heritability, including symptoms of binge eating (Reichborn-Kjennerud, Bulik, Tambs, & Harris, 2004) and indicators of eating behaviors such as emotional and uncontrolled eating (Tholin, Rasmussen, Tynelius, & Karlsson, 2005). To date, however, few studies have taken an explicit developmental perspective to examine if there are age-based changes in the etiology of eating behaviors. Two papers illustrate the potential utility of this approach. Klump, McGue, and Iacono (2000) reported that eating attitudes and behaviors were more heritable in adolescent (17-year-old) versus preadolescent (11-year-old) twins, whereas shared environmental factors were more salient in preadolescence. Further work with this sample traced the onset of heritability of eating attitudes and behaviors to the onset of puberty, as heritability could be detected in the subsample of 11-year-old twins who had reached puberty, but not in the prepubertal twins (Klump, McGue, & Iacono, 2003). Thus, a potentially important direction for future studies of eating disorders and behaviors will be tracking developmentally timed changes in the etiological contributions of genes and environment.

It is clear that behavioral genetic research has begun to make substantial progress in bringing a developmental framework to the study of psychopathology. We have focused on behavioral genetic study of symptom areas such as substance use, depression, and antisocial behavior, which has yielded especially interesting data and theory over the past decade. One additional point is that much less attention has been given to work spanning other developmental transitions, such as the progression to later life, although examples of the utility of a life span perspective are emerging (Gillespie et al., 2004). As developmental psychopathology is not synonymous with studying only childhood and adolescence,

but rather encompasses a theoretical framework concerning development through the life span, such work is also needed to further the yield of behavioral genetic research.

Elucidating Environmental Influences on Psychopathology

The developmental studies reviewed earlier highlight a tradition in behavior genetics that is now well recognized but was not always appreciated by developmentalists: Behavior genetics attempts to study both genetic and environmental influences on psychopathology. The studies discussed thus far provided evidence of environmental influences on the development of substance use, depression, and antisocial behavior. Contrary to prior decades of behavioral genetic research (e.g., Dick & Rose, 2002; Rende, 2004), the emphasis is now on shared environmental influences, environmental factors that promote similarity among family members independent of genetic influences.

New directions for studying the environment have resulted from incorporating measurable features of the environment into genetically informative designs to tease apart “pure” environmental influence that is shown to be independent of genes (e.g., Rutter, Pickles, Murray, & Eaves, 2001). There have been a wide variety of such studies in the past decade, many of which have presented evidence in favor of specific environmental contributions to psychopathology. For example, there has been interest in the broader social context, such as the neighborhood. Rose et al. (2003) have used a “double dyad” design composed of twins and their classmates to gauge effects of the neighborhood and have shown similarity of the dyads for smoking and drinking patterns, suggesting an environmental impact of the neighborhood. Caspi, Taylor, Moffitt, and Plomin (2000) used the classic twin paradigm to show that neighborhood deprivation accounted for a significant portion of the shared environmental effect on emotional and behavioral problems in toddlers. Broadening the focus on social context, Rose, Kaprio, Winter, Koskenvuo, and Viken (1999) have shown that socioregional differences strongly affect the likelihood of adolescent abstinence from alcohol and affect the extent to which abstinence aggregates in the family. These studies point to the potential impact of the broad social context that may function independently from genetic influences.

A number of studies have used similar strategies to further our knowledge of the effects of family environment on the development of psychopathology. Meyer et al. (2000) have used an extended twin-family design to show that family discord and maladaptation operate as a “true” envi-

ronmental effect, shared by family members, on antisocial behavior in childhood and adolescence. Similar support for environmental influences on antisocial behavior has come from twin studies focusing on physical maltreatment (Jaffee, Caspi, Moffitt, & Taylor, 2004) and maternal expressed emotion (Caspi et al., 2004). Jaffee et al. have shown that physical maltreatment has a direct environmental effect on antisocial behavior in childhood after controlling for the net effects of genes. They also reported that twin similarity for physical maltreatment is not due to genes but reflects the shared experiences of being in an abusive home, furthering the evidence that physical maltreatment represents an environmental influence on development. Caspi et al. utilized comparisons of MZ twins who experienced differential maternal treatment, and demonstrated that the MZ twins who received more maternal negativity and less maternal warmth had higher levels of antisocial behavior than their identical cotwins. As this design implicitly controls for genetic similarity by focusing on differences within MZ pairs, it provides direct evidence of environmental influence on antisocial behavior.

The interaction between family members has also been highlighted as a potential environmental mechanism for substance use, especially smoking. The smoking behavior of parents and siblings appears to function primarily as an environmental risk for smoking in adolescence, although some genetic effects on this relationship emerge in adulthood (Vink, Willemsen, & Boomsma, 2003). Slomkowski and coworkers (2005) have shown that this proposed sibling effect on smoking is an environmental process that is moderated by having high levels of sibling social connectedness (a composite of time spent together, mutual friendships, and warmth). Taken together, these diverse studies share the framework of using genetically informative designs to not only establish the existence of environmental effects, but to elucidate specific measurable features of the family environment that may serve as targets for intervention and prevention efforts.

A related theme to emerge from the developmental studies of psychopathology discussed earlier is the necessity to consider models that make explicit the interplay of genetic and environmental influences. Although elegant models of gene-environment interplay have been offered in behavioral genetics for over 2 decades with clear specification of the distinction between gene-environment interaction and gene-environment correlation (see Rende & Plomin, 1995), there has been an infusion of increased recognition of the importance of this topic. A number of theoretical papers devoted to gene-environment interplay have emerged in the past few years. These have included increasing recogni-

tion of the expansion of the classic twin paradigm to consider both gene-environment interaction and correlation (Kendler, 2001). Attention to the conceptual and methodological issues involved in studying gene-environment correlations and interactions particularly with respect to developmental psychopathology have also been offered (Rutter, 2002; Rutter et al., 1997; Rutter & Silberg, 2002). The importance of gene-environment interplay has been recognized for a number of domains, including Schizophrenia (Tsuang, 2000; Tsuang, Stone, & Faraone, 2001) and alcohol dependence (Heath & Nelson, 2002).

In addition to conceptual and theoretical papers, there have been a number of empirical studies that have taken on gene-environment interplay using a variety of designs. Returning to the theme of socioregional influences on alcohol use, genetic effects on adolescent drinking are more pronounced in urban versus rural settings, a form of gene-environment interaction (Dick, Rose, Viken, Kaprio, & Koskenvuo, 2001; Rose, Dick, Viken, & Kaprio, 2001). Gene-environment interaction has also been implicated for the effects of parental drinking on adolescent drinking, as there is evidence that (especially for boys) exposure to parental drinking increases heritability (Cleveland & Wiebe, 2003).

The study of gene-environment interplay and depression highlights the complexity of the issue. It has been long recognized that exposure to stressful life events increases risk for depression, both in adolescence and adulthood. Behavioral genetic approaches have been well positioned to examine mechanisms underlying this association, including both gene-environment interaction (genetic factors influence the sensitivity to life events that promotes depression) and gene-environment correlation (genetic factors contribute to exposure to life events that promote depression). Behavioral genetic studies suggest that both mechanisms may be at work. Twin studies have shown that genetic factors associated with Major Depressive Disorder are also correlated with the probability of experiencing stressful life events, particularly in the interpersonal and occupational/financial domains (Kendler & Karkowski-Shuman, 1997). Kendler et al. (1999) estimate that such gene-environment correlation accounts for about one-third of the association between stressful life events and depression, with the implication being that there are causal effects between stress exposure and depression onset. With respect to adolescent depression (particularly in girls), there is also evidence that there is an environmental pathway between exposure to life events and depression (Silberg, Rutter, Neale, et al., 2001). These studies suggest that genetic factors influence susceptibility to such exposure and that there may be correlation between

genetic factors that affect depression likelihood as well as exposure to life events.

The complexity of the pathways linking genetic susceptibility to and control over effects of the environment has also come to light in studies evaluating the effects of prenatal exposure to tobacco. Historically similar to research on life events, research on maternal smoking during the prenatal period has often been considered an environmental risk factor for behavioral problems in childhood, especially conduct problems. Behavioral genetic methodology has been used to reexamine this supposed link, opening up the possibility that some of the association may not be causal but may reflect a "spurious" association due to familial transmission of a latent "antisocial" trait that similarly influences maternal smoking and childhood conduct problems. Two studies in particular have examined this topic. Silberg et al. (2003) used a combined family-twin design to explore links between maternal smoking and childhood conduct problems; they concluded that the fundamental pathway (for boys) was genetic transmission of a latent factor that influenced expression of antisocial behavior. Maughan, Taylor, Caspi, and Moffitt (2004) also used parental data collected in a twin study of childhood and also concluded that there was evidence of correlated genetic effects. These authors highlight potential environmental confounds such as maternal mating with antisocial men and living in disadvantaged circumstances.

It is clear that current behavioral genetic theory and research has taken seriously the role of environmental influences on the development of psychopathology. The fundamental advance has come from incorporating specific measures of the environment into the classic behavioral genetic models, permitting insight into environmental effects, gene-environment interaction, and gene-environment correlation. The range of environmental factors considered to date (including socioregional and neighborhood effects, family dynamics involving parents and siblings, exposure to life stress, and prenatal exposure to tobacco) is impressive and speaks to the theory-driven nature of this work. The primary conclusion that may be reached at this point is that the impact of the environment may involve a variety of mechanisms, depending in part on the area of psychopathology being studied and the developmental epoch of interest.

Genetically Informative Designs and the Heritable Component of Behavior

The advancements made in understanding environmental contributions to the development of psychopathology have resulted in large measure from including specific dimensions

of the environment in behavioral genetic studies. A similar spirit drives the use of behavioral genetic designs to elucidate the behavioral expression of genetic influence. Indeed, it has been well recognized that a major barrier to progress is the lack of specified indicators of genetic influence for many domains of psychopathology. Work in this area is progressing in two complementary ways. One fundamental area for advance involves the identification of genetic markers along with indication of their functional significance in the brain. This topic is reviewed in the section on molecular genetics. A second area relies on the application of traditional paradigms used in behavioral genetics to elucidate behavioral indicators of the genetic signal. We focus here on this approach and review various strategies that have been used to date.

Before presenting exemplars of the behavioral genetic approach to uncovering indicators of genetic influence, we present some of the conceptual underpinnings that are especially important for this enterprise. For nearly 40 years, behavioral genetic research has promoted the concept of genetic liability to disorder as opposed to inheritance of the disorder per se (Rende & Plomin, 1995). It is noted here that the term “liability” traditionally refers either to a theoretical construct of genetic influence that is *inferred* but not measured, or to a statistical representation of the effect size of this theoretical parameter. As discussed earlier, this fundamental construct has essentially been accepted for nearly all domains of psychopathology, including rare conditions such as Autism, Schizophrenia, and Bipolar Disorder. In terms of charting progress in behavioral genetics, the construct of liability, and the statistical modeling of it using biometrical models, has essentially delivered its yield and now provides a foundation for attempts to isolate specific indicators of such liability.

In this regard, there is consensus that a critical step for behavioral genetics is to identify putative phenotypes that best reflect the expression of genes (Gottesman & Gould, 2003; Merikangas & Risch, 2003). Broad clinical descriptors such as psychiatric diagnoses represent the “end product” of gene-environment interplay and, as targets for genetic investigations, are not maximally informative about specific indicators that reside closer to the genetic signal (Gottesman & Gould, 2003; Merikangas & Risch, 2003). There have been multiple suggestions for improving the resolution of genetic studies, including genetic studies that incorporate measurement of the environment, via the refinement of “candidate phenotypes” that may be more informative of underlying genetic liability. This is precisely the area in which traditional behavioral genetic designs may shed new light on our understanding of psychopathology, if they are aimed at measurable indicators of genetic

liability to move the field closer to the putative genetic effect.

This approach is best exemplified by the search for *endophenotypes*, typically regarded as biological markers that may begin to flag the mechanisms representing genetic liability. Although there has been extensive interest in endophenotypes for decades, this area is taking on new momentum in the era of genomics research. Gottesman and Gould (2003) have provided a number of criteria that could be used to uncover so-called endophenotypes, which include traits or markers that may reflect more closely the expression of vulnerability genes (see our expanded discussion of endophenotypes in the section on molecular genetics). A similar construct with somewhat different implications is captured by the phrase *intermediate phenotype* (e.g., Enoch, Schuckit, Johnson, & Goldman, 2003). Although sometimes used interchangeably with endophenotype, this term is also used to refer to genetically driven dimensions or indicators of behavior that are conceptually tied to a domain of psychopathology without representing full expression of a diagnosed condition or syndrome. We propose that this term sometimes differs in spirit from endophenotype in that it refers more to *phenotypic* traits associated with a form of psychopathology that more closely reflect the genetic signals underlying a disorder or syndrome, as opposed to more distal biological markers of underlying genetic risk (which is the spirit of an endophenotype). We belabor this point primarily to indicate that the gene-brain system-behavior chain is complex, such that there may be many indicators of genetic contribution to psychopathology. These can range from biological markers that represent the expression of genetic risk for a disorder (such as regulation of a neurotransmitter, underlying brain pathology) to behavioral traits that better reflect phenotypic expression of genetic risk (such as being a personality trait that is highly heritable that conveys likelihood for developing a specific form of psychopathology) to identification of indicators of a disorder that appear to be more heritable than others (e.g., subtypes of a disorder, specific symptoms of a disorder).

An excellent illustration of the range of phenotypic markers that may be investigated is provided by Swan et al. (2003). With particular reference to genetic studies of tobacco use, these authors have provided a “class” system to make the point that candidate phenotypes may take many forms, including more precise clinical descriptors, underlying trait characteristics, and specific indicators of biological mechanisms. Specifically, they present four such classes, ranging from the least informative for genetic studies (Class I) to the most informative (Class IV):

Class I: Relatively crude, broad summary or cross-sectional measures of smoking behaviors, such as ever/never smoker, current/former/never smoker, age at initiation, and average number of cigarettes smoked per day.

Class II: Measures or indicators of tobacco dependence, such as time to first cigarette in the morning or number of quit attempts.

Class III: Classifications that emphasize the process of or progression toward the development of regular smoking or tobacco dependence, such as smoking topography, uptake slope, or trajectory.

Class IV: Nicotine pharmacokinetic parameters (the effects of the body on the drug, i.e., nicotine absorption, metabolism), and pharmacodynamic effects (the effects of the drug on the body, including physiological responses, heightened concentration, and changes in receptor function and density).

We thus present progress made in the field to date, being mindful of the multiple ways that behavior genetic designs can illuminate with specificity heritable underpinnings of psychopathology. One area of research continues a tradition of behavioral genetic work that attempts to understand the specificity and nonspecificity of heritable influences on psychopathology. This work serves an important function by establishing the broad landscape for genetic studies, approaching the classic issue of lumping versus splitting disorders from the perspective of etiology. *Lumping* refers to explaining the etiology of a number of disorders via common genetic influences, such as having a shared genetic etiology to comorbid disorders. *Splitting* refers to decomposing a heterogeneous disorder into etiologically independent subtypes.

A number of twin studies have begun to clarify both a common genetic vulnerability to substance use and drug-specific effects (Tsuang, Bar, et al., 2001), providing evidence in favor of lumping. For example, multivariate biometrical modeling of data collected on adult males as part of the Vietnam Era Twin Registry has shown that there is a common genetic influence that affects abusing a number of drugs, including marijuana, sedatives, stimulants, heroin, and psychedelics (Tsuang et al., 1998). Similarly, Kendler, Jacobson, Prescott, and Neale (2003) reported a singular genetic factor that influenced risk for illicit use and abuse/dependence of cannabis, cocaine, hallucinogens, sedatives, stimulants, and opiates in a study of adult male twins ascertained from the Virginia Twin Registry. There may also be a common genetic vulnerability that underlies risk for nicotine and alcohol dependence in men (True,

Xian, et al., 1999). The theme of common genetic risk has also arisen in studies of tobacco, alcohol, and caffeine (Hettema, Corey, & Kendler, 1999).

Common genetic vulnerability has been shown across a number of psychiatric disorders and domains of psychopathology. Biometrical modeling has provided evidence of shared genetic risk for the following: anorexia nervosa and Major Depressive Disorder (Wade, Bulik, Neale, & Kendler, 2000); Attention-Deficit/Hyperactivity Disorder and Oppositional-Defiant Disorder/Conduct Disorder (Nadder, Rutter, Silberg, Maes, & Eaves, 2002); Generalized Anxiety Disorder and Panic Disorder (Scherrer et al., 2000); Posttraumatic Stress Disorder, alcohol and drug dependence (Xian et al., 2000); alcohol dependence and marijuana dependence (True, Heath, et al., 1999); pathological gambling and Antisocial Personality Disorder (Slutske et al., 2001); and Major Depressive Disorder, alcohol dependence, marijuana dependence, and Antisocial Personality Disorder (Fu et al., 2002). Although some of these studies also reported evidence of disorder-specific genetic effects, it is clear that a fundamental conclusion is that the construct of lumping from the perspective of genetics is alive and flourishing.

A different approach has been taken when examining alternative phenotypes (i.e., those that might reflect genetic effects more closely than more traditional diagnostic measures). Indeed, it could be argued that the strong evidence for common genetic factors may reflect, in part, the imprecision of measurement offered by traditional diagnostic categories. Research on Attention-Deficit/Hyperactivity Disorder (ADHD) provides a good example of this tradition of searching for more heritable indicators characteristic of the splitting perspective. One approach has focused on latent class analysis of the symptoms of ADHD in twin samples, the intent being to identify empirically different classes of this syndrome and to determine if there is evidence of class-specific heritability. To date, the studies conducted support this contention and provide evidence of multiple independent forms of ADHD, reflecting subtype-specific genetic effects (Neuman et al., 2001; Rasmussen et al., 2004; Todd, Rasmussen, et al., 2001).

Similar research on other domains of psychopathology have focused on isolating more specific indicators of genetic influence than those offered by analyzing traditional diagnostic categories. Using an Australian sample of twins, Lessov et al. (2004) have reported that five symptoms of nicotine dependence (tolerance, withdrawal, experiencing difficulty quitting, time to first cigarette in the morning, and number of cigarettes smoked per day) represent the most heritable components of nicotine dependence. It has also been shown that failed smoking cessation and nicotine

withdrawal are both heritable, with partial correlation between these indicators of genetic vulnerability (Xian et al., 2003). An interesting aspect to this study is that Xian et al. focused on a subsample of twins (drawn from the Vietnam Era Twin Registry) in which both members of the twin pair were lifetime smokers and had made at least one attempt to quit smoking. This permitted a fine-grained analysis of a number of individual nicotine withdrawal symptoms. Slutske et al. (1999) analyzed the etiological architecture of a number of alcoholism symptoms and found a wide range in the resultant heritabilities (from .03 to .53). Given the overlapping confidence intervals surrounding these heritability estimates, the authors cautioned against the likelihood of identifying “more or less heritable” symptoms of alcoholism, although they noted the potential importance of pursuing this topic. Other research on alcohol disorders has shown that individual differences in alcohol intake are due to genetic effects, with additional genes contributing to alcohol dependence (Whitfield et al., 2004). This study is unique (and arguably approaches Class II phenotypes) because it utilized multiple assessments to determine repeatability of intake as the phenotype of interest.

Although a number of twin studies have shown that Major Depressive Disorder (MDD) is heritable (Sullivan et al., 2000), the family study paradigm has been informative over a number of years by documenting specific clinical features that are associated with familial aggregation. Studies using extensions of the family design have provided further clarification. In a landmark study, Weissman et al. (2005) have shown the transmission of risk for MDD across three generations. The three-generation analysis yielded two findings that build on prior research with important implications for genetic studies: (1) Rates of depression are highest in the third-generation offspring who have both parents and grandparents with moderately to severely impairing depression; and (2) Anxiety Disorders are the first manifestation of familial risk for depression. This work is critical in that it has identified clinical characteristics of depression (impairment) linked to familial transmission, expanded familial transmission across generations, and permitted insight into the developmental trajectory of risk in childhood (Anxiety Disorders) and adolescence and adulthood (depression). Similarly, Klein, Lewinsohn, Rohde, Seeley, and Durbin (2002) have found that severity of depression (involving both recurrence of episodes and impairment) is the most salient marker of familial aggregation, as opposed to specific symptoms of depression. The work of Klein and colleagues is important developmentally as they have utilized a bottom-up (see Rende & Weissman, 1999) design focusing on relatives of adolescents with

MDD (as opposed to the more traditional top-down design focused on offspring of depressed parents). Their work (see also Klein, Lewinsohn, Seeley, & Rohde, 2001) has demonstrated that depression with onset in adolescence is a highly familial phenotype and thus converges well with the more vast literature on offspring of depressed parents. Indeed, Wickramaratne, Warner, and Weissman (2000) have shown, using data from the Weissman top-down longitudinal intergenerational study mentioned earlier, that early-onset depression is heterogeneous and not informative for genetic studies without reference to familial loading. Interestingly, the converging evidence for the importance of clinical severity/impairment as a marker of familial risk for depression has also been found in analyses of twin samples (Kendler et al., 1999).

The studies reviewed in this section represent a number of ways in which behavioral genetic work has begun to unravel the etiological architecture of psychopathology. The studies discussed thus far, however, have all been focused at the level of symptomatology, and it is clear that progress in the field will come about in part by linking symptom presentation with attempts to conceptualize and measure putative endophenotypes or intermediate phenotypes. Studies focused on Obsessive-Compulsive Disorder (OCD) illustrate well how this leap may occur. There have been efforts to examine the complex spectrum of symptoms that may manifest as part of OCD and to employ statistical methods to generate a number of specific dimensions that are partly distinct etiologically. Mataix-Cols, do Rosario-Campos, and Leckman (2005) reviewed a number of factor analytic studies and derived four symptom dimensions of OCD: symmetry/ordering, hoarding, contamination/cleaning, and obsessions/checking. Of particular relevance is that these authors speculated that these symptom dimensions may represent viable endophenotypes for genetic studies of OCD. Miguel et al. (2005) have furthered this argument by proposing that dimensional components of OCD such as these may underlie the genetic contributions to distinctive phenotypic subgroups of the disorder. These models of OCD provide both a theoretical foundation for genetic studies and measurable endophenotypes that may be evaluated as indicators of genetic influence by behavioral genetic paradigms.

To date, most domains of psychopathology of interest to developmentalists are at this formative stage in terms of conceptualizing endophenotypes, a necessary step that precedes their measurement and testing in genetically informative designs. For example, research on depression, anxiety, antisocial behavior, and substance use have lagged behind progress achieved for other areas of dysfunction such as

Schizophrenia, where there is a long history of examining endophenotypes (Gottesman & Erlenmeyer-Kimling, 2001; Tsuang, 2001) and much activity in this area using both family and twin designs (Glahn et al., 2003; Seidman et al., 2002). However, two areas of research have begun to measure and test putative endophenotypes and reflect important conceptual progress. First, endophenotypic indicators of risk for ADHD have received attention. Stins, van Baal, Polderman, Verhulst, and Boomsma (2004) have used the twin paradigm to demonstrate genetic effects on performance of the Stroop task, an indicator of frontal functioning, in a large sample of 12-year-olds. They suggest that performance on this task may serve as a potential endophenotype for genetic studies of ADHD and other disorders that reflect frontal dysfunction. Nigg, Blaskey, Stawicki, and Sachek (2004) have taken a neuropsychological approach by examining executive and regulatory measures in parents and siblings of children with ADHD and have presented a neurogenetic model for a subset of executive functions. Nonaffected siblings of ADHD probands have also been shown to have a deficient response inhibition, which has been argued to represent potential genetic vulnerability to ADHD (Slaats-Willemse, Swaab-Barneveld, de Sonnevile, van der Meulen, & Buitelaar, 2003). These three studies provide prototype designs (both twin and family) with appropriate attention to specified and measurable endophenotypes. A similar spirit has guided research on reduced P300 amplitude as a potential endophenotype indexing familial (genetic) risk for alcoholism. Both family (Hesselbrock, Begleiter, Porjesz, O'Connor, & Bauer, 2001) and twin (Carlson, Iacono, & McGue, 2002, 2004) studies have supported this idea by focusing on nonaffected family members. This group of studies on alcoholism, along with the studies on ADHD, represent significant progress by explicitly testing endophenotypes using informative family and twin designs.

Method Development in Behavioral Genetics

Behavioral genetic research has always been associated with method development. For a number of years, such method development was primarily analytic, including the advent of biometrical model fitting, which became a benchmark of modern work (see Rende & Plomin, 1995). In this section, we wish to emphasize that research design represents another domain for advancement in behavior genetics. For example, historically, the twin and adoption paradigms that represented the advent of the fundamental behavioral genetic designs were expanded to include designs such as twins reared apart, sibling adoption studies, and combined

twin and sibling paradigms. A newer design of particular relevance for the study of developmental psychopathology is the children of twins paradigm.

A number of papers have argued that the children of twins design (COT) offers a unique opportunity to resolve issues pertaining to genetic and environmental transmission within families, with obvious application to developmental psychopathology. Two papers (D'Onofrio et al., 2003; Silberg & Eaves, 2004) have presented both a theoretical and an analytic framework for the COT design, and both papers have suggested that a unique contribution of this approach is the ability to differentiate environmental effects from genetic effects with more precision than is offered by more traditional behavioral genetic designs. Applications of this design have shown, for example, that the familial environment (presence or absence of exposure to parental alcoholism) moderates the expression of high genetic risk for alcoholism (Jacob et al., 2003); that prenatal exposure to tobacco represents an environmental contribution to birthweight (D'Onofrio et al., 2003); and that environmental factors (including gene-environment interplay) contribute to the association between parental alcoholism and offspring suicide attempts (Glowinski et al., 2004). Of particular interest in the COT is the focus on vertical transmission (intergenerational transmission), which is typically lacking in the traditional twin paradigm (which focuses on horizontal transmission). Thus, the COT expands the utility of the top-down or high-risk design that has played a critical role in developmental psychopathology (Rende & Weissman, 1999) by adding a genetically informative component. This combination of elements from the family and twin paradigms offers unique opportunities to understand in much greater detail the genetic and environmental mechanisms underlying transmission of familial risk for psychopathology.

Summary

This section has considered the substantial progress that has been made in the behavioral genetic study of psychopathology, especially as it relates to the fundamental tenets of developmental psychopathology. Behavioral genetic designs have been especially useful in mapping out potential etiological pathways to psychopathology that span developmental epochs (e.g., childhood to adolescence, adolescence to adulthood). We have gained much insight over the past decade on the role of environmental influences on psychopathology, particularly shared environmental effects in childhood and adolescence. Similar effort has been devoted to refining our conception and measurement of the indicators of genetic

influence on psychopathology. Finally, advances in behavioral genetic designs have also begun to make important contributions to our understanding of the development of psychopathology.

MOLECULAR GENETIC APPROACHES TO DEVELOPMENTAL PSYCHOPATHOLOGY

The previous section provides ample evidence of the contribution of behavioral genetics to our understanding of psychopathology. In addition, behavioral genetics has had a major impact on our conceptualization of genetic influence on psychiatric disease as well as helped shape the methodology used in molecular genetic studies (Rende, 2004). Indeed, behavioral and molecular genetic studies of psychopathology have become intricately linked, especially as behavioral genetic work lays a strong foundation for current molecular investigations.

Before turning exclusively to advances in molecular genetic approaches to psychopathology, we expand on the ways behavioral genetics has helped shape the focus and direction of genomic research. First, the vast empirical yield of behavioral genetic research demonstrating that heritability estimates do not fully explain the distribution of disorder in the population, even for severe diseases such as Schizophrenia and Bipolar Disorder, helped revamp genetic search strategies by changing the underlying genetic model. Specifically, the *empirical* evidence for genetic and environmental influences on nearly all forms of psychopathology gathered from behavioral genetic studies resulted in a paradigm shift in psychiatric genetics. Mendelian models of single-gene influence have been discarded in favor of multifactorial models that incorporate the effects of many probabilistic genes along with non-genetic influences, as represented in the fundamental quantitative genetic model (Rende, 2004). This shift has in fact occurred for most common diseases, of which psychiatric disorder is but one class (Conneally, 2003; Merikangas & Risch, 2003; van den Bree & Owen, 2003).

This paradigm shift is reflected in the de-emphasis (or reworking) of genetic strategies best suited for detecting single or major gene effects on disorder, in favor of alternative strategies aimed at detecting the correlation of genes of small effect size with complex disease (see Conneally, 2003; Merikangas & Risch, 2003; van den Bree & Owen, 2003). The emphasis in behavioral genetics on the complexity of the phenotype, as well as the construct of genetic liability, has also helped shape molecular studies by focusing attention on intermediate phenotypes and endophenotypes. Finally, the importance of the environment has been recog-

nized in molecular studies that assess gene-environment interaction. The progress in the field of molecular genetics that is reviewed here is thus conceptually linked with behavioral genetics by quantitative genetic theory, the theoretical foundation that has guided behavioral genetics for decades, and also logically derives from the substantial empirical findings derived from behavioral genetic studies.

Overview

Over the past decade, molecular genetic studies of psychopathology have transitioned from the potential to the real. Whereas quantitative genetic studies have increased our knowledge of the etiology of various disorders in a general manner by characterizing abstract, anonymous genetic and environmental variance components, only molecular genetic studies can point to specific genetic risk factors and their consequent etiological mechanisms. At the time the first edition to these volumes was published over a decade ago, molecular genetic studies of psychopathology represented an unrealized dream, the discussion of which was confined to the "Future Directions" section of the chapter. Much of the actualization of the potential of such studies stems from technological rather than conceptual developments. Advances in DNA collection methods using minimally invasive procedures (i.e., buccal cells versus venipuncture; Freeman et al., 1997), advances in genotyping methods (Craig & McClay, 2002), and the proliferation of DNA markers culminating in the sequencing of the human genome and successive improvements to databases in which DNA markers such as single nucleotide polymorphisms (SNPs) are catalogued (Reich, Gabriel, & Altshuler, 2003) all have contributed to the rapid progress in molecular genetic studies of various forms of psychopathology seen since the publication of the first edition of these volumes.

In this section, we first describe some fundamental aspects of the design and analysis of molecular genetic studies, including the concepts of association and linkage, the basics of genome scans and candidate gene studies, and important considerations in the search for genes that underlie complex traits (i.e., those that are thought to have multiple genetic and environmental causes). We proceed with a consideration of some of the more important themes that are emerging in molecular genetic studies of psychopathology that are important for guiding future research in this domain. These include the *replicability and consistency* of findings of association and linkage between a gene and a disorder, the *specificity* of association and/or linkage findings to particular diagnostic subtypes or symptom dimensions, and the *heterogeneity* of association and/or linkage

with a particular disorder due to characteristics of individuals such as age, sex, or age of onset or due to aspects of the environment (i.e., gene-environment interactions). The last theme involves the use of endophenotypes in molecular genetic studies of psychopathology, examining association and/or linkage with some underlying biological or psychological mechanism that is thought to more directly reflect the gene's action than does the disorder of interest. We illustrate these themes using examples from molecular genetic studies of several disorders, including ADHD, Schizophrenia, depression and Bipolar Disorder, antisocial behavior, and Autism. We focus primarily on candidate gene studies but also consider findings from genome scans where applicable. Wherever possible, we also highlight ways in which developmental psychopathology concepts can elucidate current molecular genetic findings and directions for future research. To facilitate the reading of this section, Table 10.2 presents definitions of key terms.

Association and Linkage

In contrast to behavioral genetic studies, which estimate broad, abstract components of genetic and environmental variance that contribute to the liability underlying a disorder, molecular genetic studies examine the role of specific genes or genomic regions that may contribute to the etiology of a given disorder. Molecular genetic studies of disorders test for association and/or linkage between a given disorder and particular candidate genes or genomic regions. In association studies, the frequency of high-risk and low-risk forms of a candidate gene (i.e., high- and low-risk alleles) are typically contrasted in cases and controls (i.e., individuals ascertained based on the presence of the target disorder versus a sample selected based on the absence of the disorder who are matched on a variety of background characteristics), with the expectation that cases will show higher frequencies of the high-risk allele than controls. Several variations on the classic case-control association design have been developed (e.g., a comparison of symptom levels in individuals who have 0, 1, or 2 copies of the high-risk allele of a particular gene in a nonreferred sample, or in siblings that differ in the number of high-risk alleles). One very important variation is family-based association methods, such as the haplotype-based Haplotype Relative Risk (HRRR; Falk & Rubenstein, 1987; Terwilliger & Ott, 1992), which contrast the alleles that are transmitted with those that are not transmitted by parents to their affected children. In this design, the nontransmitted alleles serve as controls for the transmitted alleles, which are expected to be high-risk alleles that are disproportionately transmitted to the affected children if there is

TABLE 10.2 A Glossary of Terms for Molecular Genetic Studies

Term	Definition
Allele	One of the alternative forms of a DNA marker.
Association	A nonrandom difference in the frequency of alternative forms of a DNA marker between individuals with and without some diagnosis or across levels of a trait.
Candidate gene study	A study that conducts a targeted test of the association of one or more DNA markers in a specific gene with a disorder or trait.
Endophenotype	Constructs posited to underlie psychiatric disorders or psychopathological traits and to be more directly influenced by the genes relevant to disorder than are the manifest symptoms.
Genome scan	An exploratory search across the whole genome for genes related to a disorder or trait.
Haplotype	A particular configuration of alleles at multiple DNA markers in close contiguity within a chromosomal region.
Knock-out gene studies	Studies in model organisms, such as mice, in which one or both copies of a gene are deactivated and the effects on behavior and/or cognition are examined.
Linkage	The correlation of a disorder and DNA markers within families, typically tested by examining the cosegregation of the presence or absence of the disorder with sharing particular allele(s) of a DNA marker.
Polymorphism	A DNA marker that varies among individuals in the population.
Population stratification	An association between a DNA marker and a disorder or trait that is not due to the causal effects of the gene, but is instead due to the mixture of subsamples (e.g., ethnic groups) that differ in both allele frequencies and symptom levels or diagnostic rates.
SNP	Single nucleotide polymorphism: a single nucleotide base that varies among individuals in the population.
Transmission Disequilibrium Test (TDT)	A within-family test of association and linkage that is robust to the potentially biasing effects of population stratification, the TDT contrasts the transmitted and nontransmitted alleles from <i>heterozygous</i> parents only (i.e., parents with two different alleles) to their children diagnosed with the target disorder.
VNTR	Variable number of tandem repeats: a DNA marker that consists of a number of base pairs that are repeated a varying number of times across individuals in the population.
UTR	An untranslated region of the gene, meaning a part of the gene that is not involved directly in the coding of proteins.

indeed an association between the disorder and the gene. Family-based association designs were developed to avoid the problem of population stratification that often can plague conventional case-control association studies, leading to false positive results. This problem occurs when case

and control samples differ not only in the rates (or symptom levels) of the disorder, but in the frequency of high- and low-risk alleles for reasons other than the causal effects of the gene on the disorder. This mixture of subsamples that differ in both allele frequencies and symptom levels/diagnostic rates induces an association in the overall sample that may occur even in the absence of any true relation between the gene and the disorder in either of the \ subsamples. The most common source of population stratification is thought to be ethnic group differences, wherein ethnic groups differ both in allele frequencies and rates of disorder, although in principle stratification effects may be due to any form of population structure (e.g., socioeconomic status differences) that varies between cases and controls. Within-family association methods are thought to avoid the biasing effects of population stratification because the transmitted and nontransmitted alleles come from the same individuals within the sample of cases.

In linkage studies, typically the correlation of a disorder and anonymous DNA markers is examined within family members (e.g., sibling pairs, parents and their children). In classical linkage studies, this involves examining the cosegregation of the presence or absence of the disorder with sharing particular alleles of a DNA marker through large family pedigrees. Note that in linkage analysis, it is commonly assumed that the anonymous DNA markers are not themselves the genes contributing to the etiology of the disorder, but may be “linked” with them due to their close contiguity on the chromosome, which results in their frequent coinheritance during meiosis. In the case of strong linkage, there is a strong co-occurrence among relatives of the presence or absence of the disorder with sharing the same DNA marker allele *identical by descent* (IBD), which means that the shared allele is not merely of the same type (*identical by state* or IBS), but is indeed the identical allele transmitted by a common ancestor. Classical linkage analyses are commonly *model-based*, meaning that the researcher must specify a number of parameters a priori, including the base rate of the disorder, the allele frequencies, and the penetrances of the genotypes. (The investigator also can examine genetic heterogeneity by modeling the proportion of families in which the disorder is linked to the genomic region.) Needless to say, in most instances, the values of most, if not all, of these parameters would be unknown. This led statistical geneticists to develop *model-free* linkage analytic methods, which require the specification of few or no parameters a priori. Model-free analyses typically are both more flexible and less powerful than model-based linkage analyses, in which values of the parameters are correctly specified. A common form of model-free linkage analysis involves esti-

imating the proportion of alleles shared IBD among affected sibling pairs for each DNA marker examined. A departure of the proportion of alleles shared IBD from the expected Mendelian proportions (namely, .25, .50, .25, for 0, 1, and 2 alleles shared IBD, respectively) suggests that the genomic region in which that DNA marker resides is linked with the disorder.

Like association analyses, linkage analyses have undergone many important refinements. First, there has been a shift in contemporary linkage studies toward the use of many smaller family pedigrees or large numbers of affected sibling pairs rather than a reliance on a few very large family pedigrees. Second, linkage analyses of specific targeted candidate genes, rather than of large numbers of anonymous DNA markers, are becoming more common. One statistical genetic tool that has become quite popular for such studies is the Transmission Disequilibrium Test (TDT; Spielman, McGinnis, & Ewens, 1993). The TDT is similar to the aforementioned HHRR, in that both statistics contrast the transmitted and nontransmitted alleles from parents to their affected children. The only methodological difference between the analytic methods is that the TDT contrasts the transmitted and nontransmitted alleles only from *heterozygous* parents (i.e., parents with one high-risk and one low-risk allele), as opposed to contrasting the alleles transmitted by all parents, as in the HHRR. Nonetheless, the TDT possesses a number of important statistical properties that distinguish it from the HHRR, including being a test of linkage as well as association, being robust to population stratification, and enabling one to include multiple affected offspring from a given family in a test of linkage. In contrast, the HHRR is a test of association only, is not completely robust to the biasing effects of population stratification, and cannot accommodate data from multiple affected offspring from the same family due to the violation of the assumption of observational independence. Given its favorable characteristics, it is little wonder that the TDT has received so much use and attention regarding its statistical properties as compared with alternative statistical genetic methods in the genetics literature. In addition, the TDT has been extended by a number of researchers (e.g., Rabinowitz, 1997; Waldman, Robinson, & Rowe, 1999) to enable the examination of linkage between a candidate gene or DNA marker and multiple continuous as well as categorical variables (e.g., symptom levels of a disorder instead of or in addition to a diagnosis).

The Genetics of Complex Traits

A number of geneticists (e.g., Chakravarti, 1999; Lander & Schork, 1994; Risch, 2000; Risch & Merikangas, 1996)

have highlighted important differences between the genetics of simple Mendelian diseases and of complex traits or disorders and have focused on the special challenges posed by the search for genes that underlie the latter. These geneticists define a *complex trait* as any phenotype that does not exhibit classic Mendelian recessive or dominant inheritance attributable to a single gene locus (Lander & Schork, 1994). Complex traits and disorders have a number of features that distinguish them from Mendelian diseases. First, complex traits are thought to result from the effects of multiple genetic and environmental influences. Second, each of the multiple genes thought to underlie complex disorders likely confers only a relatively small risk for the disorder. Third, these genes are likely to have fairly low penetrance (i.e., the probability of developing the disorder given the presence of the high-risk allele or genotype) and have a relatively high allele frequency in the population. Fourth, there is likely to be genetic heterogeneity for complex traits, such that the same genotype can result in different phenotypes (i.e., multifinality or pleiotropy) and different genotypes can result in the same phenotype (i.e., equifinality or final common pathway). Fifth, there is likely to be the presence of phenocopies (i.e., disorders caused by environmental influences that have the same symptom presentation as the inherited disorder) for complex disorders. Sixth, specific environmental influences are more likely to be important risk factors for complex disorders, and there may be the presence of gene- or genotype-by-environment interaction. Suffice to say, for complex traits and disorders it is most likely that the etiology and risk to relatives is composed of a multitude of susceptibility genes, each contributing only a small magnitude of the overall risk for the disorder. Indeed, most researchers consider the underlying causes of almost all forms of psychopathology to be polygenic (i.e., influenced by many genes and environmental factors).

Genome Scans and Candidate Gene Studies

Broadly speaking, there are two general strategies for finding genes that contribute to the etiology of a disorder. The first is a genome scan, in which linkage is examined between a disorder and a large number of DNA markers scattered at approximately equal distances across the genome. Genome scans may be thought of as exploratory searches for putative genes that contribute to the etiology of a disorder. What makes genome scans exploratory is that neither the location of the relevant genes nor their function or etiological relevance is known a priori. On the other hand, the fact that major genes have been found for many medical

diseases via genome scans is testament to the usefulness of this method. Unfortunately, the power of linkage analyses in genome scans is typically quite low, making it very difficult, if not impossible, to detect genes that account for less than ~15% of the variance in a disorder. Given this, the promise for genome scans of complex traits (e.g., disorders in which multiple genes and environmental influences contribute to their etiology) remains largely unknown.

In many ways, candidate gene studies are polar opposites of genome scans. In contrast to the exploratory nature of genome scans, well-conducted candidate gene studies represent a targeted test of the role of specific genes in the etiology of a disorder. In addition, the location, function, and etiological relevance of candidate genes is most often known or strongly hypothesized a priori, although the specific polymorphism chosen for study in the candidate gene may itself not be functional and the functional mutation(s) in the candidate gene may be as yet unidentified. A big advantage of well-conducted candidate gene studies in comparison with genome scans is that positive findings are easily interpretable because one already knows the gene's location, function, and etiological relevance. Some disadvantages of candidate gene studies are that one cannot find genes that one has not looked for; also, there are still not that many strong candidate genes for psychiatric disorders, and the same candidate genes tend to be examined for almost all psychiatric disorders, regardless of how disparate the disorders may be in terms of their symptomatology or conjectured pathophysiology. In well-designed studies, however, candidate genes are selected based on the known or strongly hypothesized role of their gene product in the etiology of the disorder (i.e., its pathophysiological function and etiological relevance). Thus, with respect to psychiatric disorders, most of the candidate genes heretofore examined underlie various aspects of disorder-relevant neurotransmitter pathways (e.g., dopaminergic candidate genes for ADHD and Schizophrenia, serotonergic candidate genes for depression and Anxiety Disorders). With regard to ADHD, for example, this is a result of the strongly conjectured role of the dopaminergic (and, to a lesser extent, noradrenergic) system in the etiology and pathophysiology of ADHD (e.g., Biederman & Spencer, 1999; F. Levy, 1991; Pliszka, McCracken, & Maas, 1996), as well as the observation that stimulant medications, the most common and effective treatment for ADHD, appear to act primarily by regulating dopamine levels in the brain (Seeman & Madras, 1998; Solanto, 1984). Another justification for the selection of ADHD candidate genes within the dopaminergic system involves the results of knock-out gene studies in mice, in which the behavioral effects of the deactivation of these genes is examined. Results of such studies

have markedly strengthened the consideration of genes within the dopaminergic system as candidate genes for ADHD, including the dopamine transporter gene (DAT1; Giros, Jaber, Jones, Wightman, & Caron, 1996), and the dopamine receptor D3 and D4 genes (DRD3 and DRD4; Accili et al., 1996; Dulawa, Grandy, Low, Paulus, & Geyer, 1999; Rubenstein et al., 1997).

To address the four aforementioned themes in this section of the chapter, we review various studies of association and linkage between psychiatric disorders and candidate genes within neurotransmission pathways. Candidate genes for neurotransmitter systems may include (1) *precursor genes* that affect the rate at which neurotransmitters are produced from precursor amino acids (e.g., tyrosine hydroxylase for dopamine and tryptophan hydroxylase for serotonin); (2) *receptor genes* that are involved in receiving neurotransmitter signals (e.g., genes corresponding to the five dopamine receptors, DRD1, D2, D3, D4, and D5, and to the numerous serotonin receptors); (3) *transporter genes* that are involved in the reuptake of neurotransmitters back into the presynaptic terminal (e.g., the dopamine transporter gene, DAT1, and the serotonin transporter gene, 5HTT); (4) *metabolite genes* that are involved in the metabolism or degradation of these neurotransmitters (e.g., the gene for catechol-O-methyltransferase, COMT, and for monoamine oxidase A and B, MAOA and MAOB); and (5) genes that are responsible for the *conversion* of one neurotransmitter into another (e.g., dopamine beta hydroxylase, or DbH, which converts dopamine into norepinephrine).

Studies of association and linkage between psychiatric disorders and candidate genes, as well as genome scans for these disorders, are appearing in the literature at an accelerating rate; thus, this review is necessarily somewhat incomplete. Rather than attempting a comprehensive review of all candidate gene studies and genome scans for all psychiatric disorders, we selectively review such studies to illustrate the burgeoning investigation of the four overarching themes mentioned earlier, which we feel provide a meaningful structure for exploring etiology in developmental psychopathology studies.

Replicability and Consistency of Findings

Perhaps the greatest challenge of molecular genetic studies of complex traits and disorders is replication. Numerous researchers have raised concerns regarding the replication of association and linkage findings for both psychiatric disorders and medical diseases (e.g., Crowe, 1993; Kidd, 1993).

At the extreme, the editors of certain journals have decided to ban case-control association studies or association findings from a single sample unaccompanied by evidence for replication. Indeed, for almost any psychiatric disorder and any associated candidate gene or linked genomic region studied, there are both positive and negative findings published. It may be cold comfort to recognize that such mixed findings are by no means the exclusive province of psychiatric genetics, as medical genetic studies also have found failures to replicate (e.g., linkage findings for Type I diabetes; Concannon et al., 1998). To render this phenomenon of mixed findings more tangible, we provide a number of examples from studies of association and linkage for several psychiatric disorders. We begin by discussing the results of candidate gene studies of the dopamine receptor D4 gene (i.e., DRD4) and ADHD, given that this is perhaps the most frequently studied candidate gene for ADHD and that it well illustrates both the difficulties of interpreting such mixed findings and the aid that meta-analysis can provide toward that end. We then proceed to discuss the first two genome scans for ADHD and their (almost totally) nonoverlapping findings, as well as the conclusions from meta-analyses of genome scans for Schizophrenia and Bipolar Disorder.

Attention-Deficit/Hyperactivity Disorder and the Dopamine Receptor D4 Gene

Initial interest in DRD4 as a candidate gene for ADHD was sparked by association studies that linked the gene to the personality trait of novelty seeking (Benjamin et al., 1996; Ebstein et al., 1996), which has been compared to the high levels of impulsivity and excitability often seen in ADHD. Further interest in DRD4 as a candidate gene for ADHD has been generated from knock-out mouse studies. Rubenstein et al. (1997) compared the behavior of homozygous DRD4 knock-out mice and wild-type controls following administration of cocaine and methamphetamine and noted that the knock-out mice showed a heightened response to cocaine and methamphetamine injection relative to controls, as measured by increases in locomotor behavior. In addition, several studies have suggested that the 7-repeat of a 48 base pair VNTR (i.e., variable number of tandem repeats) in exon 3 of the gene differs, albeit slightly, from the 2- and 4-repeats in secondary messenger (i.e., cAMP) activity and possibly also in response to the antipsychotic medication clozapine (Ashgari et al., 1994, 1995).

Such findings suggest the potential involvement of DRD4 in the pathophysiology of ADHD; thus, LaHoste et al. (1996) conducted an association study of DRD4 with

ADHD in children in a small case-control sample ($n = 39$ cases and 39 ethnically matched controls). The authors reported increased prevalence of the 7-repeat allele and genotype in cases (29% and 49%, respectively) compared to controls (12% and 21%, respectively). A number of replication studies have investigated the relation between the exon 3 VNTR of DRD4 and ADHD (7 case-control and 14 within-family studies), the findings and methods of which have been described in a number of reviews (Swanson et al., 1998; Thapar, Holmes, Poulton, & Harrington, 1999). The findings of association between ADHD and DRD4 were replicated in some of these studies but not in others, and thus, it is noteworthy that there is a meta-analysis of these case-control and within-family association studies (Faraone, Doyle, Mick, & Biederman, 2001), which demonstrated a significant DRD4-ADHD association for both types of studies (case-control: $p = .00000008$; relative risk = 1.9, 95% CI: 1.4 to 2.2; within-family: $p = .02$; relative risk = 1.4, 95% CI: 1.1 to 1.6). Although the evidence was notably stronger for the case-control studies, it is possible that this is the result of biasing effects of population stratification or some other systematic difference, such as greater power for case-control than within-family designs. Since the publication of this meta-analysis, two additional studies have been published examining the relation between the exon 3 VNTR of DRD4 and ADHD. The first study reported increased prevalence of the 7-repeat allele in a clinical sample compared to a control group (Roman et al., 2001), whereas the second study reported significant preferential nontransmission of the 7-repeat allele to ADHD offspring (Manor et al., 2002). These conflicting findings further demonstrate the importance of meta-analysis for integrating such data when studying the genetic basis of complex disorders such as ADHD.

Population Samples

In addition to examining the relation of DRD4 to ADHD when defined as a discrete diagnostic category, researchers have investigated whether DRD4 might influence specific behavioral traits that are continuously distributed in the population and that, at their extreme end, are thought to represent ADHD. For example, Curran et al. (2001) tested for association between the exon 3 VNTR of DRD4 and severity of ADHD symptoms, which were assessed by questionnaire and defined along a continuum, in a large epidemiological sample. The authors selected for their sample children who scored at either the high or low extreme end of this continuum and reported that the 7-repeat

allele was significantly more prevalent among high scorers than low scorers ($\chi^2 = 8.63$, $p = .003$, Odds ratio = 2.09). In a similar study, Mill et al. (2002) tested the relation between the exon 3 VNTR of DRD4 and ratings of hyperactive and impulsive behaviors in a sample of 1,037 children participating in a longitudinal study. The children were assessed at ages 7, 9, 11, 13, and 15. Rather than dichotomizing their sample, Mill et al. used the continuous symptom scores to test for association between the 7-repeat allele and each behavioral dimension. The authors reported no evidence for association between DRD4 and either behavioral trait at any of the assessment points. Thus, the two studies reviewed show conflicting results regarding the association between DRD4 and hyperactive-impulsive behavior in the general population.

Other researchers have investigated the relation between DRD4 and the normal development of attention processes. Auerbach, Benjamin, Faroy, Geller, and Ebstein (2001) assessed sustained attention abilities using an orientation task in a sample of 64 1-year-old infants. The authors reported that infants with the 7-repeat allele took significantly longer to orient to objects and showed significantly shorter periods of focused attention on these objects than infants without the 7-repeat allele ($F(1,55) = 4.65$, Effect size = .074 and $F(1,55) = 8.06$, Effect size = .120, respectively). In a sample of older children, Schmidt, Fox, Pérez-Edgar, Hu, and Hamer (2001) tested the relation between the DRD4 exon 3 VNTR and inattention as assessed by the Attention Problems subscale of the Child Behavior Checklist (Achenbach & Edelbrock, 1981). As part of a longitudinal study, the authors collected data on a population sample of 174 children at age 4 and age 7. Association analyses showed a relation between the 7-repeat allele and increased attention problems at age 4 ($F(1,159) = 4.79$, $p = .030$, Standardized mean difference = 0.35) and age 7 ($F(1,106) = 4.16$, $p = .044$, Standardized mean difference = 0.40) such that children with one or more copies of the 7-repeat allele had higher scores than children with no copies. These two studies demonstrate a relation between the DRD4 exon 3 VNTR and the development of attention processes in the normal population.

Multimarker Data

Our review of studies testing for linkage and association between DRD4 and ADHD has thus far been limited to studies that have tested this relation using only the exon 3 VNTR. A number of studies have tested for linkage and association at additional polymorphisms within DRD4, and some of these studies have created haplotypes using

these markers to test for the presence of susceptibility loci for ADHD. Barr and colleagues (2000, 2001) examined the relation between DRD4 and ADHD at three loci in addition to the exon 3 VNTR. In the first published study, the authors genotyped subjects at the VNTR, a mononucleotide repeat in intron 1, and a 12-bp repeat in exon 1. In addition to the significant linkage result with the 7-repeat allele of the exon 3 VNTR (previously reported in Sunohara et al., 2000), the authors reported a trend for linkage between the 142-bp allele of the intron 1 mononucleotide repeat ($\chi^2 = 3.57$, $p = .059$, Relative risk = 0.65) but not for either allele of the exon 1 12-bp repeat ($\chi^2 = 0.43$, $p = .513$, Relative risk = 1.33; Barr et al., 2000). Of particular importance, haplotypes constructed from genotypes at these three markers showed strong evidence for linkage between DRD4 and ADHD, with a haplotype containing the exon 3 7-repeat allele and the intron 1 140-bp allele showing preferential transmission to affected children ($\chi^2 = 4.90$, $p = .027$, Relative risk = 2.08). In a subsequent study, Barr et al. (2001) tested for linkage with ADHD at three additional polymorphisms located in the 5' UTR of DRD4. These polymorphisms included a 120-bp repeat 1.2 kb upstream of the transcription start site and two SNPs also upstream from the start site at positions -521 and -616. The authors reported a trend for linkage between the 1-repeat allele of the 120-bp repeat and ADHD ($\chi^2 = 1.66$, $p = .198$, Relative risk = 1.35) as well as the SNP at position -616 ($\chi^2 = 2.04$, $p = .154$, Relative risk = 1.37). There was no evidence of linkage between ADHD and the SNP at position -521 ($\chi^2 = 0.818$, $p = .366$, Relative risk = 1.20). Although none of the haplotypes containing alleles suggestive of linkage with ADHD in the single marker analyses showed preferential transmission to affected children, one haplotype containing the opposite alleles at the two markers that were suggestive of linkage did show a trend toward preferential nontransmission ($\chi^2 = 3.571$, $p = .059$, Relative risk = 2.11). Thus, these studies further support a relation between DRD4 and ADHD.

In addition to the studies by Barr et al. (2001), three other research groups have examined the relation between ADHD and DRD4 polymorphisms other than the exon 3 VNTR. McCracken et al. (2000) tested for linkage at the 120-bp repeat in the 5' UTR of DRD4 described earlier (Barr et al., 2001). The authors reported significant preferential transmission of the 2-repeat allele to affected offspring ($\chi^2 = 5.40$, $p = .020$, Relative risk = 1.35), and this relation strengthened when the sample was restricted to include only children with Inattentive ADHD subtype ($\chi^2 = 8.00$, $p = .005$, Relative risk = 1.80). Nonetheless, it should be noted that it was the 1-repeat allele, and not the 2-repeat

allele, that showed a trend toward preferential transmission in the study by Barr et al. (2001). In addition to single marker analyses, McCracken et al. also conducted haplotype analyses using genotypic data from the 5' UTR repeat and the exon 3 VNTR. These analyses revealed a trend for preferential transmission of a haplotype containing both the 7-repeat allele of the exon 3 VNTR and the 2-repeat allele of the 5' UTR repeat ($\chi^2 = 1.92$, $p = .165$, Relative risk = 1.29), and the significant preferential nontransmission of a haplotype containing non-7-repeat alleles of the exon 3 VNTR and the 1-repeat allele of the 5' UTR repeat ($\chi^2 = 4.17$, $p = .040$, Relative risk = 0.72).

In a similar study, Todd, Neuman, et al. (2001) tested for association at the exon 3 VNTR and the 5' UTR repeat in a sample of twins drawn from the general population. In contrast to the previously reviewed study, Todd et al. did not find evidence suggestive of linkage at either individual marker (exon 3 7-repeat: $\chi^2 = 0.30$, $p = .58$, Relative risk = 1.11; 5' UTR 1-repeat: $\chi^2 = 0.59$, $p = .44$, Relative risk = 1.16). They did report significant preferential transmission of a haplotype containing both the 7-repeat allele of the exon 3 VNTR and the 1-repeat allele of the 5' UTR repeat ($\chi^2 = 4.45$, $p = .04$, Relative risk = 4.50), but this result became nonsignificant when they corrected for conducting multiple tests (adjusted $p = .25$).

The final study to test for linkage between a DRD4 polymorphism other than the exon 3 VNTR and ADHD was conducted by Payton et al. (2001). The authors genotyped subjects at the 5' UTR SNP at position -521 described earlier (Barr et al., 2001), and similar to that study, they reported no evidence for association between this 5' UTR DRD4 SNP and ADHD ($\chi^2 = 0.19$, $p = .75$, Relative risk = 1.10).

To summarize, the meta-analysis conducted by Faraone et al. (2001) suggests a strong relation between the 7-repeat allele of the exon 3 VNTR of DRD4. In addition, studies testing the relation in the general population between behaviors associated with ADHD such as hyperactivity and sustained attention abilities support the hypothesis that DRD4 may influence these traits in normal development and not just in children with ADHD. Finally, despite the conflicting results across some of the reviewed studies, examinations of multiple markers within DRD4 are beginning to provide additional data that may lead to a better understanding of the relation between DRD4 and ADHD.

This difficulty in making sense of the mixed findings from candidate gene studies is not limited to the association and linkage between ADHD and DRD4. For example, numerous studies have been conducted of the association between Schizophrenia and the dopamine receptor D3 gene

(DRD3) and the serotonin receptor 2A gene (HTR2A), with the predictable pattern of mixed findings. Meta-analyses of these associations were conducted (Williams, McGuffin, Nothen, & Owen, 1997; Williams et al., 1998) and detected significant associations across studies, despite the fact that the magnitude of these associations was fairly modest (i.e., Odds Ratios \cong 1.3). An informal perusal of results of these studies might (incorrectly) conclude that association between these genes and Schizophrenia is absent, thus highlighting the importance of formal, statistical evaluations of the associations across studies using meta-analysis. In addition to serving as an effective mechanism for combining results and testing their significance across studies, meta-analytic procedures also provide an estimate of the magnitude of association, quantify the degree of heterogeneity in the effect sizes across studies, and can include moderator variables that may meaningfully explain any variability observed in the effect sizes across studies. Such moderators can represent either important substantive variables (e.g., representation of diagnostic subtypes, rates of comorbid disorders) or methodological features (e.g., male:female ratios, location of the study) that differ across studies.

Problems in interpreting the results of molecular genetic studies are not limited to candidate gene studies of association. For example, two genome scans for ADHD have been published (Bakker et al., 2003; Ogdie et al., 2003) that examined allele sharing in affected sibling pairs with an average marker spacing of \sim 10 cM. Ogdie et al. examined linkage in 270 affected sib pairs from 204 families in the United States and found linkage on the short arm of chromosome 16 (16p13), suggestive linkage on the short arm of chromosome 17 (17p11), and nominal (i.e., weaker) support for linkage in four additional chromosomal regions (i.e., on the short arm of chromosome 5 [5p13] and on the long arms of chromosomes 6, 11, and 20 [6q14, 11q25, and 20q13]). Bakker et al. examined linkage in 164 affected sib pairs in 106 Dutch families and found suggestive linkage to two regions, the long arm of chromosome 15 (15q15.1) and the short arm of chromosome 7 (7p13), and nominal support for linkage in seven additional chromosomal regions (3q13.32, 4p16.3, 5p13.1, 6q26, 9q33.3, 10cen, and 13q33.3). It is noteworthy that only one of these chromosomal regions (5p13) showed linkage in both the U.S. and Dutch samples and that evidence for linkage to the remaining 13 chromosomal regions was found in one of the samples but not the other. These linkage findings again highlight the difficulties inherent in drawing inferences regarding linkage from a few studies with relatively small samples, in which it is

likely that the genomic regions suggestive of linkage will differ appreciably across studies *for statistical reasons alone*. That is, although there may be other reasons for the discrepant findings across these two studies, such as differences in the populations sampled or in the assessment or diagnostic methods used, the stochastic fluctuations associated with few studies of small sample size are sufficient to cause such discrepancies.

In contrast to ADHD, many more genome scans have been conducted for Schizophrenia, Bipolar Disorder, and Autism. Nonetheless, a casual perusal of the scans for these disorders would lead to a similar impression as that for the scans of ADHD, namely, that there is greater *nonoverlap* than there is overlap of the genomic regions of interest across studies. Indeed, some reviewers of the numerous genome scans for Schizophrenia have stated that the available evidence from all of these studies provides about as much support for linkage at almost any location in the genome as evidence against linkage at these same genomic locations! Fortunately, methods for the meta-analysis of genome scans have been developed (e.g., Badner & Gershon, 2002b; Wise, Lanchbury, & Lewis, 1999) and applied to the genome scans for Schizophrenia, Bipolar Disorder, and Autism. In contrast to the apparently inconsistent picture of results yielded by conventional reviews of these studies, meta-analyses yield a more consistent and coherent summary of the findings. For example, one of the most exciting findings in psychiatric genetics is the linkage of Autism to the long arm of chromosome 7 (7q), as well as the observation that this linkage finding appeared to replicate across a few independent studies. Nonetheless, Hutcherson et al. (2003) simultaneously analyzed the 7q linkage data from multiple samples but were unable to find a specific narrow location that was common across studies or an associated polymorphism that explained the linkage to the 7q region. Fortunately, a meta-analysis of four genome scans (Badner & Gershon, 2002b) yielded convincing evidence for the replication of the linkage of Autism to the 7q region. Indeed, this was the only genomic region for which linkage findings replicated across the four genome scans.

For Schizophrenia, a meta-analysis of 20 genome scans found significant linkages on the short arms of chromosomes 3, 6, 8, 10, and 14 and on the long arms of chromosomes 1, 5, 6, 11, 15, 16, 17, 18, 20, and 22 (Lewis et al., 2003). For Bipolar Disorder, a meta-analysis of 18 genome scans found significant linkages on the short arms of chromosomes 9 and 18 and the long arms of chromosomes 8, 10, 14, and 18 (Segurado et al., 2003). Although the findings from these meta-analyses suggest greater consistency in the results of genome scans for these disorders, particularly

Schizophrenia, than do previous reviews, even the results of such meta-analyses are somewhat dependent on the particular meta-analytic methods employed. For example, using an alternative meta-analytic method on published genome scans, Badner and Gershon (2002a) found significant replicable results for both Schizophrenia and Bipolar Disorder only on the long arms of chromosomes 13 and 22, and for Schizophrenia also on the short arm of chromosome 8. Although the meta-analytic methods used in these studies differed substantially, it is noteworthy that only one location (22q for Schizophrenia) was identified by both methods. These results reinforce the notion that, though useful, meta-analyses are not a magic wand for detecting replicable linkage findings across studies. In addition, even in the presence of replicated linkage findings, it can be very difficult to narrow down the specific chromosomal location that harbors the particular candidate gene of interest (Roberts, MacLean, Neale, Eaves, & Kendler, 1999), the necessary step in identifying the particular genetic risk factor that contributes to the etiology of the disorder.

Specificity of Findings to Diagnostic Subtypes or Symptom Dimensions

Although replication of association and linkage findings is essential for establishing the validity of the relations between genes and disorders, they may not be particularly informative regarding the specific phenotype(s) influenced by the gene. Following the example mentioned earlier, the demonstration of replicated association between DRD4 and ADHD across studies does not inform us as to whether DRD4 is also a risk factor for the other disruptive disorders (i.e., Oppositional Defiant Disorder and Conduct Disorder) that have been shown to substantially overlap with ADHD both phenotypically and genetically (e.g., Biederman, Newcorn, & Sprich, 1991; Waldman, Rhee, Levy, & Hay, 2001), or whether the effects of DRD4 on ADHD are actually more specific, being confined to a particular diagnostic subtype or symptom dimension. Indeed, this difference in approaches corresponds to the lumping versus splitting distinction that has long characterized much research in a variety of psychopathology domains. For example, some researchers examining the genetics of such disorders in both quantitative and molecular genetic studies have argued for the lumping approach that transcends specific disorders in favor of a broad externalizing dimension (Krueger et al., 2002; S. E. Young et al., 2002), whereas other researchers have demonstrated the benefits of examining the genetics of specific diagnostic subtypes or symptom dimensions (Lowe et al.,

2004; Waldman et al., 1998). In our view, it is likely that there is merit in pursuing both approaches, given that some genes may act in a pleiotropic manner to confer risk on a number of related disorders, whereas other genes may be quite specific in their influence, by demonstrating effects only on a particular facet of a single disorder. We provide some tangible examples to help illustrate these different possibilities.

Specificity in Association and Linkage between Dopamine Genes and Attention-Deficit/Hyperactivity Disorder

Several candidate gene studies of ADHD have examined the specificity of association and/or linkage findings to particular diagnostic subtypes or symptom dimensions. The conceptual rationale underlying such studies is that it is highly unlikely that whatever genes confer risk for ADHD work at the level of the overall diagnosis, and that nature so closely resembles the current version of the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*. We think it is much more likely that whatever genes contribute to risk for ADHD do so by conferring risk for specific diagnostic subtypes or symptom dimensions. Although this area of molecular genetic research is only in its infancy, there have been a few examples of such findings in this research domain. For example, Waldman et al. (1998) found that DAT1 is associated and linked with the Combined subtype, but not the Inattentive subtype, and appears to be related more strongly to hyperactive-impulsive than inattentive symptoms of the disorder. Similarly, Eisenberg et al. (1999) reported an association between the valine/valine genotype of COMT and the Hyperactive-Impulsive and Combined, but not the Inattentive, ADHD subtypes. In contrast, Lowe et al. (2004) found that the association and linkage between DRD5 and ADHD was significant for the Combined and Inattentive subtypes, but not for the Hyperactive-Impulsive subtype. Holmes et al. (2002) found that DRD4 is related to ADHD only when it is accompanied by Conduct Disorder. Although other researchers have focused on examining genetic influences on higher-order diagnostic constructs, such as an externalizing symptom dimension (e.g., Krueger et al., 2002; S. E. Young et al., 2002), and have advocated the utility of studying the genetics of broad diagnostic constructs that span several *DSM-IV* diagnoses, we believe that these results for ADHD suggest that examining association and linkage with more specific diagnostic subtypes or symptom dimensions also will be a fruitful approach. Pursuing both of these possibilities simultaneously in a two-pronged approach is ideal, given the primitive stage of our knowledge

of the association between specific genes and disorders and the likelihood that some genes will be risk factors for several related disorders, whereas others will confer risk only on narrower disorder phenotypes.

Specificity of genetic influences to diagnostic subtypes or symptom dimensions in the psychiatric genetics literature is not confined to studies of ADHD or to studies of association with candidate genes. For example, in molecular genetic studies of Schizophrenia, one of the several studies reporting linkage to the short arm of chromosome 6 analyzed quantitative Schizophrenia symptom dimensions in addition to the diagnosis of Schizophrenia (Brzustowicz et al., 1997) and found linkage with positive but not negative symptoms. Similarly, in linkage studies of reading disability (e.g., Fisher et al., 1999; Grigorenko et al., 1997), linkage findings appeared to be specific to different reading disability phenotypes on chromosome 6p (phonological awareness, phonological decoding, and irregular word reading) versus 15q (single-word reading). The linkage findings for chromosome 6p were replicated in two independent family samples (Fisher et al., 1999; Gayan et al., 1999) but failed to replicate in a third sample (Field & Kaplan, 1998). These studies suggest that dissecting the Schizophrenia and reading disability phenotypes into more specific components, as well as examining the manifest diagnosis, may help significantly in finding susceptibility loci for these (and other) disorders. In the meta-analysis of genome scans of Bipolar Disorder described earlier (Segurado et al., 2003), different genomic regions were found to be linked with somewhat different Bipolar Disorder diagnostic phenotypes. Whereas a region on the long arm of chromosome 14 was found to be linked with Bipolar Disorder I, Schizoaffective Disorder-Bipolar type, and Bipolar Disorder II, regions on the short arm of chromosome 9 and the long arm of chromosome 10 were found to be linked only with Bipolar Disorder I and Schizoaffective Disorder-Bipolar type (Segurado et al., 2003). In addition, nominally significant evidence for linkage was found for all of these diagnostic phenotypes and for recurrent Major Depression on chromosome 18 (Segurado et al., 2003). Similarly, in a multisite candidate gene study examining association and linkage between the dopamine transporter gene (DAT1) and Bipolar Disorder diagnostic phenotypes (Waldman, Robinson, & Feigon, 1997), the relation between this gene and the disorder varied by the breadth of the Bipolar Disorder diagnostic phenotype examined. Specifically, in a sample from Cardiff, Wales, DAT1 appeared to be associated and linked with a narrow Bipolar Disorder diagnostic phenotype comprising Bipolar Disorder I and II, whereas in a

sample from San Diego, DAT1 appeared to be associated and linked with a broad Bipolar Disorder diagnostic phenotype comprising not only Bipolar Disorder I and II but also recurrent unipolar depression.

Focus on Alternative Pathways Underlying Psychopathological and Normal Development

It is also worth noting that the lumping versus splitting distinction bears some similarities to developmental psychopathologists' differentiation among a number of alternative pathways that individuals' development may take. In particular, developmental psychopathologists make use of the terms *equifinality* and *multifinality*, developed in general systems theory (von Bertalanffy, 1968; as cited in Cicchetti & Rogosch, 1996, 1999), to refer to two general types of developmental pathways. *Equifinality* refers to the scenario where several distinct causes or developmental processes can eventuate in the same outcome, whereas *multifinality* refers to the scenario where a particular cause or developmental process can result in a multiplicity of outcomes (Cicchetti & Rogosch, 1996, 1999). *Equifinality* is quite similar to the concept of "final common pathway" that is discussed in many accounts of the etiology of psychopathology. An example of this is if multiple genes within the dopaminergic neurotransmitter system conferred risk for ADHD in an interchangeable manner, such that having the high-risk alleles for any of a critical number of these genes would be more important than having high-risk alleles for a particular subset of such genes. *Multifinality* occurs when the same causal process or developmental event differs in its effects or outcome, depending on other causes, developmental contexts, or an individual's choices (Cicchetti & Rogosch, 1996). Many readers will note that multifinality can thus be construed as an example of moderation, in which the relation between a cause and some outcome varies depending on other factors, which can be studied and modeled in appropriate analyses. An example of multifinality mentioned earlier is the finding that DRD4 may be a risk factor for ADHD only when it is accompanied by Conduct Disorder (Holmes et al., 2002). If replicated, this would indicate that the role of DRD4 as a risk factor for ADHD differs as a function of developmental context, namely, the presence or absence of overlapping Conduct Disorder. Other examples of multifinality are better construed as cases of heterogeneity, to be discussed later. These might include gene-gene and gene-environment interactions, in which the role of a given genetic risk factor for the development of a disorder might differ as a function of the allele(s) at another gene(s) or aspects of the environment to which the individual is exposed.

Focus on Continuities and Discontinuities between Normal and Abnormal Development

Developmental psychopathologists also are quite cognizant of the fact that an individual's developmental outcome (e.g., diagnostic status for some disorder) is not static but can change over time and place (Cicchetti, 1993; Sroufe & Rutter, 1984). Consistent with this is the recognition that an individual's diagnostic status is somewhat arbitrary, based on surpassing a prespecified diagnostic threshold. Given what at times are only minor differences in the symptom levels of individuals above and below the diagnostic threshold, developmental psychopathologists are interested in the similarities and differences in adjustment between such individuals. This is only one example of developmental psychopathologists' interest in the continuities and discontinuities between normal and abnormal adjustment. Another example concerns the extent to which the causes of an abnormal developmental outcome (e.g., a disorder such as ADHD) are the same or different from those of the corresponding normal range trait (e.g., the temperamental trait of activity level). Consistent with this notion are findings of associations between several candidate genes that are related to ADHD (e.g., DRD4, 5HTT) and normal-range traits such as activity levels and attention in young children (e.g., Auerbach et al., 2001).

Heterogeneity of Findings Based on Characteristics of Participants or Environments

A third theme important for future studies of candidate genes or genomic loci and developmental psychopathological disorders and traits involves the heterogeneity of association and/or linkage due to characteristics of individuals such as age, sex, or age of onset or due to aspects of the environment (i.e., gene-environment interactions). Just as it is implausible that the *DSM* is so closely aligned with nature that associations with candidate genes will be found only or primarily with *DSM* diagnoses, as opposed to more specific diagnostic subtypes or symptom dimensions, it is equally implausible that such associations will be equal for males and females, younger and older individuals, individuals whose disorders onset at younger and at older ages, and individuals who are exposed to widely disparate environmental contexts. Although there is at present a limited literature on such moderators of the relations between candidate genes or genomic loci and psychiatric disorders or psychopathological traits, there is considerable interest in such effects, and this literature is burgeoning. In this section, we review several studies that examined differ-

ences in association and linkage between disorders and candidate genes or genomic loci as a function of sex, age, age of onset, or environmental context.

Surprisingly few molecular genetic studies of psychiatric disorders or developmental psychopathological traits have examined such sources of heterogeneity, particularly given research showing that several candidate genes show important sex or age differences in expression. In the dopamine system, for example, levels of the dopamine transporter have been shown to be higher in males than females (e.g., Mozley, Gur, Mozley, & Gur, 2001) and to decline appreciably with age (e.g., Volkow et al., 1994). Similarly, in a study of knock-out mice in which one copy of the COMT gene was deactivated, motor activity, aggression, anxiety, and dopamine levels in the prefrontal cortex differed substantially between males and females (Gogos et al., 1998). Despite these findings, none of the published studies of DAT1 and ADHD have examined sex or age differences in association. Studies of association and linkage between COMT and ADHD have yielded mixed findings. In one study (Qian et al., 2003), however, analyses were conducted separately by sex and suggested sexually dimorphic findings, with the low-activity methionine allele being associated with ADHD in boys but the high-activity valine allele being associated with ADHD in girls. Although these results are preliminary, confined to one study, and need to be replicated, they embody the type of heterogeneity analyses that we believe may be useful for elaborating the nature of the relations between candidate genes and psychiatric disorders and developmental psychopathological traits.

Other sources of heterogeneity also may be important from a genetic perspective. In the medical genetics literature, for example, several genes are risk factors for disorder or disease contingent on age of onset. The first genetic locus found to contribute to breast cancer (i.e., BRCA1) was found to be linked with the disease only once early-onset cases were clearly distinguished from late-onset cases in the linkage analysis (Hall et al., 1990). Similarly, several genes for Alzheimer's disease (i.e., APP, APOE, PSEN1, and PSEN2) were identified as risk factors only for the early-onset form of the disease (Crutz & Van Broeckhoven, 1998). Despite these findings, to our knowledge no published candidate gene study of ADHD or any other developmental disorder has examined whether findings of association vary by age of onset. Another important source of heterogeneity may be the parent who transmitted a particular risk allele. Such transmitting parent effects are interesting from a genetic perspective because they may represent cases of imprinting, in which one parental allele

has been deactivated due to methylation. Few studies have examined transmitting parent effects on candidate genes for ADHD or other psychiatric disorders. Kirley et al. (2002) tested transmitting parent effects for several candidate genes in the dopaminergic system and found that association and linkage between ADHD and tyrosine hydroxylase (TH) and, to a lesser extent, the dopamine receptor D2 gene (DRD2) was stronger for paternally than maternally transmitted alleles.

Although developmental psychopathology researchers have long been excited by the prospect of gene-environment interaction, and many have contended that one cannot understand the development of psychopathology without the consideration of such processes, there are few published studies of gene-environment interactions for psychiatric disorders or developmental psychopathological traits. There have been two high-profile published examples of gene-environment interactions for psychopathology that have garnered considerable attention and interest (Caspi et al., 2002, 2003). In the first of these, risk for adolescent serious antisocial behavior and violence based on abuse during early childhood was found to depend on alleles at the monoamine oxidase A gene (MAOA; Caspi et al., 2002). In the second, risk for depression during early adulthood was a multiplicative function of both life stress and alleles at the serotonin transporter gene (5HTT; Caspi et al., 2003). Notable features of these studies were the careful measurement of both the psychopathology outcomes and the environmental risk factors, as well as the use of functional mutations in both candidate genes. In addition, it is important to recognize the symmetrical nature of such gene-environment interactions, that is, that gene-environment interaction refers both to the moderation of the effects of environmental risk factors as a function of individuals' genotypes at a particular gene and to the moderation of individuals' genetic predispositions for a certain disorder or trait as a function of the environmental facets to which they are exposed and that they experience. Although no gene-environment interactions for developmental disorders such as ADHD have been examined to date, it would be easy to test whether the effects of various of the candidate genes mentioned earlier differ as a function of environmental risk factors, such as pre- or perinatal complications, maternal smoking or drinking during pregnancy, or other relevant environmental risk factors that have been posited and/or studied in the literature.

Focus on Resilience and Risk

Developmental psychopathologists are interested in, and frequently examine the role of, risk factors in the develop-

ment of psychopathology; they are also interested in resilience. Resilience may be construed as the ability of individuals to attain adequate developmental outcomes, despite their having experienced various risk factors or adverse experiences at an earlier developmental stage. Developmental psychopathologists are thus interested in studying the pathways to adaptive outcomes of individuals at risk for psychopathology (e.g., Rolf, Masten, Cicchetti, Nuechterlein, & Weintraub, 1990) and of those who grow up in contexts that are extremely stressful or even abusive (e.g., Cicchetti, Rogosch, Lynch, & Holt, 1993; Masten & Coatsworth, 1998). Developmental psychopathologists also acknowledge that individuals may traverse developmental pathways that cycle between adaptive and maladaptive outcomes (Cicchetti & Richters, 1993), and they are interested in studying the dynamic aspects of these straight and deviant pathways (Robins & Rutter, 1990). In its most basic form, the concept of resilience can thus also be construed as a form of moderation, similar to multifinality, in which the relation between a risk factor and an outcome variable differs as a function of some protective factor. It would be fairly easy and straightforward to extend both the concept and design of gene-environment interaction studies to explicitly incorporate tests of resilience as well as risk factor models. The investigations by Caspi and colleagues (2002, 2003) cited earlier represent first steps in this direction of examining gene-environment interactions within a developmental psychopathology context.

The Use of Endophenotypes to Aid in Finding Genes for Disorders

Many studies of risk factors for psychopathology are limited to examining the association between a particular risk factor and a disorder. A developmental psychopathology approach attempts to transcend these simple associations in several ways. First, developmental psychopathologists strive to design their studies not only to establish an association between a disorder and one or more risk factors, but also to be informative regarding the specific causal mechanisms that underlie such associations. Hence, a focus on neurodevelopmental endophenotypic mechanisms underlying the development of psychopathology is well in keeping with this perspective. Second, most studies of the etiology of psychopathology can be best thought of as snapshots of development, given that they characterize individual participants' outcomes at a particular developmental point in time. Even in the absence of longitudinal data, developmental psychopathologists strive to place their etiological findings in proper developmental perspective.

The fifth and final theme involves the use of endophenotypes in molecular genetic studies of psychiatric disorders and developmental psychopathological traits. Clearly, there is a large gap between candidate genes and the manifest symptoms of disorders as typically assessed by interviews or rating scales. It is desirable from both a conceptual and an empirical perspective to find valid and meaningful mediational or intervening constructs that may help to bridge this gap. The term endophenotype is often used to describe such constructs and the variables that are used to measure them. Endophenotypes were first described with respect to psychiatric disorders by Gottesman and Shields (1972, p. 637) over 30 years ago in their application to the genetics of Schizophrenia as “internal phenotypes discoverable by a biochemical test or microscopic examination” (Gottesman & Gould, 2003). More generally, endophenotypes refer to constructs that are thought to underlie psychiatric disorders or psychopathological traits and to be more directly influenced by the genes relevant to disorder than are the manifest symptoms. As such, they are closer to the immediate products of such genes (i.e., the proteins they code for) and are thought to be more strongly influenced by the genes that underlie them than the manifest symptoms that they in turn undergird. Endophenotypes also are thought to be “genetically simpler” in their etiology than are complex traits such as manifest disorders or their symptom dimensions (Gottesman & Gould, 2003). This means that the underlying structure of genetic influences on endophenotypes is simpler than that of complex disorders and traits in that there are fewer individual genes (or sets thereof) that contribute to their etiology.

A number of researchers have outlined criteria for evaluating the validity and utility of putative endophenotypes (e.g., Castellanos & Tannock, 2002; Doyle et al., in press; Gottesman & Gould, 2003; Waldman, in press). These include the following: (1) The endophenotype is related to the disorder and its symptoms in the general population; (2) the endophenotype is heritable; (3) the endophenotype is expressed regardless of whether the disorder is present; (4) the endophenotype and disorder are associated within families (i.e., they cosegregate); and (5) in addition to the endophenotype occurring in family members with a disorder to a greater extent than in family members who are unaffected (viz., criteria 4), it also will occur in the unaffected relatives of family members with a disorder at a higher rate than in randomly selected individuals from the general population (given that the endophenotype reflects the inherited liability to a disorder).

In addition to these criteria, several other criteria are pertinent to the validity and utility of endophenotypes.

First, it is important that the genetic influences that underlie the endophenotype also underlie the disorder and that at least some (but likely not all) of the genetic influences that underlie the disorder underlie the endophenotype. Note that this last criterion is asymmetrical, in that a higher proportion of the genetic influences on the endophenotype will be shared in common with those on the disorder, rather than vice versa. This criterion follows from the notion mentioned earlier that endophenotypes are thought to be genetically simpler than are complex traits such as disorders, in the sense that fewer genes contribute a greater magnitude to their etiology (Gottesman & Gould, 2003). Second, measures of the endophenotype must show association and/or linkage with one (or more) of the candidate genes or genetic loci that underlie the disorder. Third, the endophenotype measure must *mediate* the association and/or linkage between the candidate gene or genetic locus and the disorder, meaning that the effects of a particular gene or locus on a disorder are expressed—either in full or in part—through the endophenotype. The prerequisites for this causal scenario are that the candidate gene influences both the disorder and the endophenotype and that the endophenotype influences the disorder.

Putative endophenotypes have begun to be used in genetic studies of a number of disorders and developmental psychopathological traits, and the validity and utility of such endophenotypes have begun to be investigated. For example, the use and evaluation of putative endophenotypes in studies of the genetics of ADHD is in its infancy, such that only a few studies have examined association and linkage between candidate genes and plausible measures of endophenotypes for ADHD. In one of the first candidate gene studies of ADHD endophenotypes, Swanson et al. (2000) examined association of the 7-repeat allele of the 48 base pair VNTR in exon 3 of DRD4 in a small sample of 32 ADHD children. Surprisingly, the authors found that although ADHD children with the 7-repeat allele exhibited hyperactive-impulsive behaviors typical of the disorder, their performance on reaction time tasks of attention resembled that of non-ADHD children, whereas children without the DRD4 7-repeat allele showed slower reaction time deficits. In one study (Langley et al., 2004), association between the 7-repeat allele and several neuropsychological tests of executive function endophenotypes was assessed in a sample of 133 6- to 13-year-old drug naïve ADHD children. These tests included a continuous performance test (CPT), the Matching Familiar Figures Test (MFFT), a Go/No Go task, and the Stop Task. Consistent with predictions, ADHD children with one or more copies of the 7-repeat allele committed more errors on the MFFT

and showed faster reaction times on the Stop Task and when committing errors on the MFFT.

In another study, Loo et al. (2003) examined association between the DAT1 10-repeat allele of the 3' UTR VNTR and both cognitive and psychophysiological endophenotypes in a sample of 27 children with ADHD. Children with 2 copies of the 10-repeat allele performed worse than children with 0 or 1 copy on various CPT measures, including signal detection indices of inattention and impulsivity, omission and commission errors, and reaction time variability. In addition, children with 2 copies of the 10-repeat allele differed from children with 0 or 1 copy in their psychophysiological response to stimulant medication, such that children with 2 copies showed greater increases in EEG indices of cortical activation and arousal on stimulant medication relative to baseline. Several other studies have provided suggestive evidence for association between candidate genes and endophenotype measures. In a study of ADHD and COMT, Eisenberg et al. (1999) found a trend for greater CPT false alarms in children with the val/val genotype than in children with the met/met genotype. It is noteworthy that the val/val genotype also was overrepresented in ADHD children with the Combined and Hyperactive-Impulsive subtypes. Finally, in a sample of 200 nonreferred adults, Fossella et al. (2002) reported associations between the index of executive control on the Attention Network Task and polymorphisms in DRD4 and MAOA. Polymorphisms in MAOA were also associated with the alerting component of the Attention Network Task. It would be interesting for future studies to attempt to replicate such findings in clinical samples of children with ADHD.

As stated earlier, a prerequisite for the validity and utility of putative endophenotype measures is their heritability and the overlap of their genetic influences with those on the disorder of interest. Similar to molecular genetic studies of association and linkage between candidate genes and endophenotypic measures, quantitative genetic studies of the heritability of such measures and of the etiology of their overlap with ADHD symptoms also are in their infancy. As such, these studies have tended to include very small samples of twins drawn from either nonreferred adult or child populations (e.g., Fan, Wu, Fossella, & Posner, 2001; Holmes et al., 2002) or a mixture of nondisordered and ADHD child populations (Kuntsi & Stevenson, 2001). Likely due to the conjunction of very small twin samples and the distributional shortcomings of the endophenotypic measures (e.g., significant nonnormality, the presence of dramatic outliers, ceiling effects), some of these studies have yielded anomalous findings, which include near-zero

and negative heritabilities (Fan et al., 2001; Kuntsi & Stevenson, 2001), enormous confidence intervals around the genetic and environmental parameter estimates and/or twin correlations (Fan et al., 2001; Holmes et al., 2002; Kuntsi & Stevenson, 2001), and negative MZ and DZ twin correlations (Holmes et al., 2002). Although estimation of the heritability of endophenotypic measures and of the magnitude of overlapping genetic influences with disorder are important steps in evaluating the validity and utility of putative endophenotypes, these extant studies represent merely the beginning of such research. Specifically, future studies must be conducted on much larger twin samples, using a broader range of endophenotypic measures, with greater attention paid to the distributional and psychometric properties of such measures. Similar criteria apply to future studies of association and linkage between ADHD candidate genes and putative endophenotypic measures.

Fortunately, the investigation of putative endophenotypes is much more developed for other disorders, Schizophrenia in particular. A number of psychophysiological and cognitive-neuropsychological endophenotypic constructs have been investigated for Schizophrenia, including sensorimotor gating, smooth pursuit eye-tracking, and working memory. Given that this literature has been reviewed in detail by Gottesman and Gould (2003), we provide only a brief summary here. Studies of sensorimotor gating have documented deficits in P50 suppression among both schizophrenic patients and their unaffected first-degree relatives (e.g., Siegel, Waldo, Mizner, Adler, & Freedman, 1984). This index has been shown to be heritable in twin studies (e.g., D. A. Young, Waldo, Rutledge, & Freedman, 1996) and has been used to find linkage to a region on chromosome 15 (Freedman et al., 1997) and association and linkage with the $\alpha 7$ nicotinic acetylcholine receptor gene that resides in this chromosomal location (Leonard et al., 2002). Deficits in smooth pursuit eye movements have been shown in both schizophrenic patients and their unaffected first-degree relatives and to be heritable in twin studies (Conklin, Curtis, Katsanis, & Iacono, 2000) and has been found to be linked with a region on the short arm of chromosome 6, for which linkage has been replicated across multiple genome scans of Schizophrenia (Arolt et al., 1996). Finally, the endophenotypic findings pertinent to Schizophrenia that have received the most attention in the literature concern the relations among the disorder, neuropsychological and brain imaging indices of working memory, and the gene for COMT, which is the major mechanism of control of dopamine levels in the prefrontal cortex. Several studies have implicated working memory deficits in both schizophrenic patients and their unaffected

first-degree relatives (e.g., Conklin et al., 2000), as well as the heritability of such measures in twin studies (Cannon et al., 2000) and have demonstrated the primacy of dorsolateral prefrontal cortical regions to working memory function in general (R. Levy & Goldman-Rakic, 2000) and to schizophrenic patients' deficits therein (Egan et al., 2001; Manoach et al., 2000). The gene for COMT is located on the long arm of chromosome 22, a location that has been linked to Schizophrenia in several genome scans, and COMT itself has shown association and linkage with Schizophrenia in several studies (Karayiorgou et al., 1995, 1998). In one study (Egan et al., 2001), COMT was associated and linked with performance on the Wisconsin Card Sorting test, a commonly used measure of working memory, and functional magnetic resonance imaging indices of activity in the dorsolateral prefrontal cortex in schizophrenic patients, their unaffected first-degree relatives, and unselected controls. The bridges built among several of the criteria for the validity and utility of putative endophenotypes go a long way toward establishing sensorimotor gating, smooth pursuit eye-tracking, and working memory as useful endophenotypes. The burgeoning literatures on endophenotypes for other disorders, such as childhood ADHD, can benefit considerably by emulating the research designs and methods used in the literature on Schizophrenia endophenotypes.

Summary

In this section of the chapter, we have tried to summarize some of the most exciting developments in molecular genetic studies of developmental psychopathology and specific psychiatric disorders. Rather than merely reviewing extant findings for several disorders, we have focused on several emerging themes in these literatures that should guide future research. These themes included the *replicability and consistency* of findings of association and linkage between a gene and a disorder, the *specificity* of association and/or linkage findings to particular diagnostic subtypes or symptom dimensions, the *heterogeneity* of association and/or linkage with a particular disorder due to characteristics of individuals or to aspects of their environments (i.e., gene-environment interactions), and the use of *endophenotypes* (i.e., underlying biological or psychological mechanisms thought to more directly reflect the gene's action) in molecular genetic studies of psychopathology. We illustrated these themes using examples from molecular genetic studies of several disorders, including ADHD, Schizophrenia, Major Depression, Bipolar Disorder, antisocial behavior, and Autism. It is our hope that these themes not

only provide a glimpse of the extant molecular genetic research on psychopathology and its development, but will help to set the research agendas for future such studies.

FUTURE DIRECTIONS

The wealth of approaches and information reviewed in this chapter set the stage for a potentially critical next decade of research in behavioral and molecular genetics. Over the past decade, it has become clear that the mission of both behavioral and molecular genetics is to increase our understanding of *mechanisms* that influence the course of adaptive and maladaptive behavior throughout the life span, rather than document empirically the extent to which genetic and environmental influences impact different forms of psychopathology. These mechanisms have begun to be specified in terms of genetic loci, specific environmental influences, and examples of gene-environment interplay. In this spirit, we speculate on the critical areas for investigation that will further our understanding of developmental processes.

At the center of future research will be the continued effort to conduct genomic research on psychopathology. In predicting the next decade, a brief consideration of the past 2 decades is informative. As we entered the 1990s, excitement lay in the idea of identifying specific genes responsible for the etiology of many diseases, including psychiatric disorders. This excitement soon waned, however, as it became clear that many diseases had complex etiologies involving both multiple genetic loci and many environmental influences. Excitement was generated again, however, by embracing the quantitative genetic model to incorporate both conceptual and methodological approaches geared toward such elusive probabilistic effects. Indeed, much of this chapter has been devoted to the execution of this goal, with many fine examples from both behavioral genetic and molecular genetic paradigms. The conceptual convergence of approaches of work reviewed in this chapter supports the contention that there is general agreement that the quantitative genetic model (i.e., a multifactorial model that includes multiple genetic and environmental effects along with the possibility of gene-environment interplay) provides to date the best representation of the etiology of most forms of psychopathology.

The fundamental issue facing the field now, however, is the extent to which we can empirically make substantial inroads that will further our understanding of development and pathogenesis. For example, it is currently recognized that progress in molecular genetics has gone slower than may have been anticipated (Plomin & McGuffin, 2003)

and that the study of genetic influences on complex diseases poses a number of difficulties and complexities (Conneally, 2003; van den Bree & Owen, 2003). Furthermore, the extent to which genomics research will have a major impact on our understanding of psychopathology has been questioned (Merikangas & Risch, 2003), and the rationale driving genomic search strategies has been challenged with a perspective informed by considerations of public health impact (Merikangas & Risch, 2003). It is thus fair to say that although the conceptual model driving genomic research on psychopathology is not questioned, there are many concerns about our ability as a field to make true inroads over the next decade.

It is always clear that technological and analytic advances may propel new directions of research, especially in fields such as genetics. Speculation on what these advances may be are beyond the scope of this chapter, but it is reasonable to suggest the possibility that our approach to understanding genetic influence will be altered, to some degree, by advances in genomics, including developments pertaining to the analysis of genetic effects. However, given this, it will be critical that the field of genomics seriously considers critiques such as those offered by Merikangas and Risch (2003, 2004) and that behavioral and molecular genetics devise well-defined and rational strategies to combat the complexities inherent in studying complex phenotypes such as psychopathology.

Given these considerations, we postulate that many of the advances over the next decade will not necessarily come from molecular genetics, but rather from new applications of behavioral genetics that may set the stage for future progress on the genomic front. We are still at a relatively crude stage in our understanding, conceptualization, and measurement of phenotypes that will provide solid targets for genomic investigations. We have reviewed a number of approaches that have been used to define, refine, and create phenotypes that reside closer to the putative genetic signals that family, twin, and adoption paradigms have detected for decades. There is still a surprising lack of attention to identifying and testing endophenotypes for many forms of psychopathology, and we speculate that this area of investigation will produce much greater yields over the next decade. In particular, it is hoped that the field that relies on quantitative genetic theory will focus intensive effort on elucidating the nebulous construct of “genetic liability” that has provided the foundation for most work conducted in psychopathology over the past few decades. We have already described the ways endophenotypes have begun to be targets for molecular genetic investigations; as more progress is made in the conceptualization, measurement, and

testing of endophenotypes using behavioral genetic strategies, it will surely improve the fruitful translation to genomic search strategies.

In this regard, it is imperative, and thus a target for future directions, that behavioral genetic research becomes more interdisciplinary, with more explicit links with cognitive, biological, and brain sciences. Integration of both additional perspectives and methodologies into genetically informative designs clearly hold promise for generating new models of risk mechanisms that reside between the gene and the phenotype. Some examples of such endophenotypes were presented in this chapter; these are clearly needed for essentially all forms of developmental psychopathology. Furthermore, as represented in some of the research on ADHD, alcoholism, and Obsessive-Compulsive Disorder, establishing links between different endophenotypes and varying clinical characteristics may revamp our understanding of etiology and provide newer and more rational targets for molecular studies. It is not far-fetched to speculate that molecular genetic studies may be better served by focusing on underlying endophenotypic processes that have a multitude of connections with a number of clinical conditions and symptom profiles. As the variety and complexity of measures increase in behavioral and molecular genetics, it will be imperative to also begin to consider approaches such as multiple levels of analysis to fully take advantage of the range of biological and psychological systems implicated in the development of psychopathology (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002).

Thus far, we have considered future directions that pertain to genetic influence. It is clear from the studies reviewed in this chapter that there is particular excitement concerning the use of genetically informative designs to elucidate environmental influences and, specifically, more “pure” indices of the environment. We have cited many examples coming from studies using traditional approaches such as twin and twin-sibling designs as well as evidence deriving from newer paradigms such as the children of twins design. Given that quantitative genetic theory, and behavioral genetics as a field, has always devoted as much attention to the environment as the genome, this is probably not surprising. However, it is especially interesting that such a focus not only continues but arguably expands in the genomic era (Merikangas, 2005), and it is assumed that future work will further this emphasis on the environment. Indeed, much of the progress made over the past decade has resulted from inclusion of measured environmental risks that were of clear theoretical importance to the domain of interest (again paralleling the inclusion of putative genetic

risk in the form of genetic markers). Thus, behavioral genetics has not just provided evidence of the importance of the environment, but in fact has begun to fill in the black box with specific indicators of environmental effects, ranging from family dynamics to neighborhood and cultural influences. We note here that the measurement of the environment in behavioral genetic studies may also, like the measurement of the phenotype, be subject to conceptual and methodological advances. We anticipate that progress over the next decade will come about by further development of our ability to measure environmental process. For example, behavioral genetic work on the family environment has begun to incorporate a variety of methodologies (e.g., self-report, videotaped interactions); such attention to the environment will undoubtedly expand our understanding of nongenetic influences on development (Neiderhiser et al., 2004; Reiss et al., 2001; Rende, Slomkowski, Lloyd-Richardson, & Niaura, 2005).

It is also clear that methodologies are being directed at understanding gene-environment interplay both in behavioral genetic and molecular genetic designs. Such work is critical, especially as intriguing conceptual models for gene-environment interplay (e.g., gene-environment interaction, gene-environment correlation) have been available for over 2 decades. Current molecular studies emphasizing gene-environment interaction (Caspi et al., 2002, 2003) are important reminders that examining main effects of genes must be complemented by other strategies that examine how genetic risk is expressed in environmental context. In addition to further study of gene-environment interaction, we also anticipate more emphasis on gene-environment correlation, especially as this topic has received much attention over the past 2 decades as having particular relevance to behavior, development, and psychopathology.

As the field moves toward a better understanding of genetic and environmental mechanisms, it is anticipated that more satisfying developmental models will follow. We presented a number of studies that have begun to sketch out the developmental trajectory for a number of forms of psychopathology, and these set the stage well for more mechanistic studies that indicate not only the *how* but the *when* of potential risk factors and their consequences. It is clear that much of the work in behavioral genetics has reflected a developmental sensitivity, and it appears as if many investigations are contributing to the construction of etiological models that extend across different developmental epochs. For example, we noted how research on depression has focused on early manifestations of familial risk in childhood (in the form of Anxiety Disorders) and

has, through the use of longitudinal and multigenerational studies, studied trajectories of such risk through adulthood. Studies focused on substance use offer another example of how behavioral genetic research has begun to identify developmental pathways. An especially exciting area for future studies will be examining how specific environmental influences and endophenotypes come together developmentally. For example, although endophenotypes are purported to represent the genetic signal, this should not be misinterpreted to mean that such signals are necessarily present early in life, and then interact with later environmental influences (although this may be a plausible model for some forms of psychopathology). Environmental influences may operate early in the life span and in fact predate the emergence of endophenotypes, such as emerging cognitive abilities that arise in the transitions to adolescence and adulthood. Incorporating a developmental perspective will undoubtedly expand our understanding of endophenotypes, environmental influence, and mechanisms of risk for psychopathology.

One final direction concerns implications for intervention. To date, there have been limited attempts to translate behavioral genetic findings into intervention models, with, of course, even fewer attempts to do so from molecular genetic studies. However, given the assumption that the next decade will yield many more insights into the processes by which genes and environment influence risk for and protection from psychopathology, along with the potential critical periods of influence, it will become a critical concern to translate these findings into intervention programs. Many opportunities present currently, especially in the form of specifying environmental effects on psychopathology. For example, there is robust and replicable evidence from a number of behavioral genetic studies that shared environmental effects are of critical importance for the initiation of substance use in adolescence, as well as exemplars of potential mechanisms for such influence. To make this point concrete, we have reviewed a number of studies demonstrating shared environmental effects on smoking initiation in adolescence, which, as argued by McGue et al. (2002), provides a solid foundation for intervention studies. Recent research has identified sibling influences as one such mechanism that reflects the impact of shared environment after controlling for genetic effects (Slomkowski et al., 2005). Thus, prevention programs that target transmission of smoking from older to younger siblings may be able to focus on a number of mechanisms that could reduce the likelihood of younger sibling smoking (Rende, Slomkowski, Lloyd-Richardson, et al., 2005). This is just one example of how

behavioral genetic research can begin to move from etiological models emphasizing classes of effects (genetic versus environmental) to work that identifies putative mechanisms that operate at potentially critical developmental periods. Although the translation of research on genetic effects to implications for intervention must await further progress, it may be argued that genetically informative designs have already provided information that could begin to filter into intervention strategies. Such an end result would clearly demonstrate the utility of behavioral and molecular genetic research on developmental psychopathology and will represent perhaps the most important direction for future research.

SUMMARY AND FUTURE DIRECTIONS	492
REFERENCES	493

Cicchetti and Toth (1995) have described two major goals of a developmental approach to psychopathology. The first is to study the development of individual capacities across the life span. The second is to examine the relation between outcomes and earlier adaptations in functioning, considering distal as well as proximal influences on development. A temperament approach to development and psychopathology is concerned with the constitutionally based dispositions that underlie the individual's social and emotional development. Temperament also provides a view of distal influence that is evolutionary in scope, identifying variations in affective-motivational and attentional adaptations to human life that are both inherited and shaped by experience. Along with attention, these include emotion related to threatening input that organizes motor and autonomic circuits to support avoidant behavior and perceptual path-

ways to enhance information relevant to threat and safety (Derryberry & Rothbart, 1984; Derryberry & Tucker, 1992; Gray, 1982; Ohman, 2000). They also include affect related to incentives that support approach, perceptual pathways that enhance information relevant to reward, and affect related to goal blockage and loss that supports attack and withdrawal.

Except in rare cases, we all exhibit these adaptations, and we share a number of them with nonhuman animals (Panksepp, 1998). Individuals vary in the reactivity of their affective motivational systems and in the self-regulatory capacities, such as attention, that modulate them (Rothbart & Derryberry, 1981). As the child develops, initially more reactive forms of regulation such as approach and fearful inhibition are increasingly supplemented by capacities of voluntary or effortful control

(Posner & Rothbart, 1998; Rothbart & Bates, 1998). These patterns of regulation may “promote a progressive stabilization of synapses within the brain, contributing to the structural organizations central to personality” (Derryberry & Reed, 1994, p. 633). The self-organization of social and emotional development based on temperament and experience provides a further proximal basis for thinking about psychopathology and its development (Cicchetti & Tucker, 1994).

In this chapter, we consider relations between temperament and the development of psychopathology. We define temperament as constitutionally based individual differences in reactivity and self-regulation, as observed in the domains of emotionality, motor activity, and attention (Rothbart, 1989c; Rothbart & Derryberry, 1981). By reactivity, we mean characteristics of the individual’s responsiveness to changes in stimulation, as reflected in somatic, autonomic, and endocrine nervous systems. By self-regulation, we mean processes modulating this reactivity, including behavioral approach, avoidance, inhibition, and attentional self-regulation. In our view, individual differences in temperament constitute the earliest expression of personality and the substrate from which later personality develops. By tracing the development of temperament and the adaptations it supports across different periods of the life span, we can illuminate our understanding of the development of risk for psychopathology.

In the previous edition of this chapter (Rothbart, Posner, & Hershey, 1995), we identified a number of ways that temperament might shape individual adaptation and vice versa. These include (1) individual differences that in the extreme may constitute the psychopathology or dispose the person toward it; (2) characteristics evoking reactions in others that can promote the risk of psychopathology or buffer it; (3) characteristics influencing the person’s “niche picking,” putting him or her at greater or lesser risk for psychopathology; (4) temperamental influences on the form of a disorder, its course, and the likelihood of its recurrence; (5) temperamental biases in information processing about the self and the world, increasing or decreasing the likelihood of psychopathology; (6) temperamental regulation or buffering against the effects of risk factors or stress; (7) temperamental heightened responsiveness to environmental events; and (8) interaction among temperament systems, some of them later developing. Two major temperamental control systems are fear, developing late in the 1st year, inhibiting approach and expressive tendencies, and effortful control, developing during the preschool years and beyond. In addition, (9) temperamental dispositions may shape different devel-

opmental pathways to a given outcome, and individual dispositions may allow for multiple outcomes (Cicchetti & Cohen, 1995). Finally, (10) temperament characteristics and caregiving environment may make independent contributions to outcomes or may interact in increasing or decreasing risk of disorder; and (11) disorders themselves may change aspects of temperament. We have been impressed at the number of studies during the past decade that speak to these issues, and we revisit them in the course of our discussion.

This chapter has two major sections. In the first, we describe findings on individual differences in temperament and attention and consider their links to neural networks. We then discuss theories and research relating temperament to the development of risk conditions for psychopathology. Individual differences in attentional capacities, a major aspect of temperament, are critical to our understanding of these issues.

We begin the chapter with a brief historical introduction, followed by a discussion of dimensions of temperament that have emerged from conceptual and factor-analytic studies of temperament early in life (Bates, Freeland, & Lounsbury, 1979; Hagekull & Bohlin, 1981; Rothbart, 1981; Sanson, Prior, Garino, Oberklaid, & Sewell, 1987). These dimensions include fear (distress and behavioral inhibition to novelty), anger or irritability, positive affect and approach, activity level, and attentional persistence. We note similarities between these dimensions and the “Big Five” and “Big Three” personality factors identified in research on adults (Goldberg, 1990). We then consider temperament dimensions in connection with models for developmental psychopathology and review recent research on temperament, attention, and the development of psychopathology.

HISTORICAL APPROACHES

We begin our brief history with a discussion of temperament typologies. We then consider factor analytic approaches to the study of temperament.

The Greco-Roman Typology

The ancient Western typology of temperament was developed by Greek and Greco-Roman physicians, including Theophrastus, Vindician, and Galen (S. Diamond, 1974). Like later approaches to temperament, the fourfold typology related individual differences in behavior and emotionality to variability in the human constitution as it was

understood at the time. The temperamental syndrome of *melancholia* (a tendency to negative and depressed mood) and its relation to a predominance of black bile was developed in the fourth century B.C. writings of Theophrastus, and the complete fourfold typology of temperament as linked to the Hippocratic bodily humors was present by the time of Vindician in the fourth century A.D. (S. Diamond, 1974).

In addition to the melancholic type, the fourfold typology included descriptions of the *choleric* person (quick-tempered and touchy, easily aroused to anger, with a predominance of yellow bile), the *phlegmatic* (apathetic and sluggish, not easily stirred to emotion, with a predominance of phlegm), and the *sanguine* person (characterized by warmth, optimism, and lively expressiveness, with a predominance of blood). The fourfold temperament typology was endorsed throughout the Middle Ages and Renaissance (cf. Burton, 1621/1921; Culpeper, 1657) and discussed by Kant (1798/1978). More recently, Eysenck's (1970) work made use of the typology, and Merenda (1987) has argued that it constitutes a four-factor model for our current understanding of temperament and personality. Recently, Watson and Clark (1995) discussed the melancholic temperament in connection with links between negative emotionality and psychopathology.

If we look at woodcuts from the Middle Ages representing the four temperament types, the behaviors depicted often do appear pathological. The choleric man is depicted beating a woman, the phlegmatic person is asleep in bed while others are working, and the melancholic person is seen in depressed attitude or portrayed as a distraught lover (e.g., Carlson, 1984, p. 613). The sanguine type is often depicted as better adjusted than the other three, but even the sanguine individual may be shown overeating or overdrinking. These images suggest that, at the extreme, individual differences in temperament may in themselves constitute maladaptations. One of the issues immediately raised by these historical treatments of temperament and psychopathology is thus the relation between a temperamental extreme and a psychopathological condition.

The Typological Approach of Carl Jung

In this century, the type construct has been modified conceptually, resulting in dimensional and factor-analytically derived approaches to an understanding of individual differences. Even the psychological types put forward by Jung (1923) differ in important ways from the fourfold typology. To Jung, introverted and extraverted qualities were pre-

dominant human attitudes, related to thinking, feeling, sensation, and intuition. Unlike the ancients, or Kagan's (1989) view of inhibited and uninhibited types as qualitatively different classes of individuals, Jung did not view psychological types as representing qualitative differences. Instead, he described them as "Galtonian family portraits, which sum up in a cumulative image the common and therefore typical characters, stressing these disproportionately, while the individual features are just as disproportionately effaced" (1923, p. 513).

Jung's approach to the type is similar to the idea of the prototype in cognition (Posner & Keele, 1968; Rosch, 1973); it is also related to principles of trait measurement. In deriving a score for an individual on a temperament or personality trait, the individual's item scores on a scale are aggregated to describe a single score that represents similarity of response across time and situations. This trait score can be seen as the *individual's* "common and therefore typical" characteristics, "stressing these disproportionately"; the influence of particular situations or other important factors is also "just as disproportionately effaced." The type can then be seen as a set of traits that tend to occur together in groups of individuals. Factor-analytic approaches to temperament and personality identify clusters of characteristics that tend to covary; results of this work are described in more detail later.

Jung also suggested that introverted *and* extraverted tendencies are present in all persons, but, for a given person, one attitude tends to become more elaborated and conscious, while the other is less elaborated, more primitive, and, for the most part, unconscious. Differentiation between extraversion and introversion, he wrote, can be seen early in life:

The earliest mark of extraversion in a child is his quick adaptation to the environment, and the extraordinary attention he gives to objects, especially to his effect upon them. Shyness in regard to objects is very slight; the child moves and lives among them with trust. He makes quick perceptions, but in a haphazard way. Apparently he develops more quickly than an introverted child, since he is less cautious, and as a rule, has no fear. Apparently, too, he feels no barrier between himself and objects, and hence he can play with them freely and learn through them. He gladly pushes his undertakings to an extreme, and risks himself in the attempt. Everything unknown seems alluring. (1928/1953, p. 303)

As objects, Jung (1923) included both physical and social entities, so that the more introverted child would show a tendency to dislike new social situations, approaching strangers with caution or fear, and the introverted adult to

dislike new situations or social gatherings, demonstrating hesitation and reserve. Jung suggests that the introvert would also be inclined toward pessimism about the outcome of future events. The extraverted person would show more ready approach and action toward social and physical objects (impulsivity) and greater sociability and optimism about the future.

Jung also related extraversion-introversion to psychopathology. He took over a distinction between two types of neurosis put forward by Janet and developed the idea that the extravert is predisposed to hysteria, “characterized by an exaggerated rapport with the members of his circle, and a frankly imitative accommodation to surrounding conditions” (Jung, 1923, p. 421), combined with a tendency toward experiencing somatic disorders. The introvert was seen as prone to psychasthenia, “a malady which is characterized on the one hand by an extreme sensitiveness, on the other by a great liability to exhaustion and chronic fatigue” (p. 479).

Factor-Analytic Studies

Extraversion-introversion also emerged from factor-analytic studies of temperament in adults. Early factor-analytic studies were carried out in Great Britain by Webb and Burt. Webb (1915) analyzed items assessing emotionality, activity, qualities of the self, and intelligence, and identified two factors. One he labeled “w,” defined as “consistency of action resulting from deliberate volition or will” (p. 34). This factor bears similarities to the higher-order personality factor recently labeled control, constraint, or conscientiousness (Digman & Inouye, 1986) and to temperamental effortful control. A second factor assessed negative emotionality, sometimes labeled emotional stability-instability; Eysenck would later call it neuroticism. By 1938, Burt had also identified the factor of extraversion-introversion. Later factor-analytic work has repeatedly identified three factors similar to these: extraversion (the first factor that is usually extracted from a large data set of personality descriptors), neuroticism, and conscientiousness (Costa & McCrae, 1988; Goldberg, 1990; John, 1989). These three factors, with the additional factors of agreeableness and openness to experience, as derived from factor analyses on trait descriptive words and personality items, constitute what have been called the Big Five personality factors.

In Eysenck’s (1944, 1947) early factor-analytic work on male neurotic subjects, factors of extraversion-introversion and neuroticism were extracted. He also reported support for Jung’s distinction between more extraverted (hysteric) symptoms and more introverted (dysthymic or psychas-

thetic) symptoms in neurosis. Eysenck (1947) also reviewed results of a factor analysis of Ackerson’s (1942) data describing a large sample of children studied by the Illinois Institute for Juvenile Research. These data yielded a general neuroticism factor, along with a factor that distinguished between more introverted behavior problems “(sensitive, absent-minded, seclusive, depressed, daydreams, inefficient, queer, inferiority feelings, and nervous), and extraverted behavior problems (such as stealing, truancy from home and school, destructive, lying, swearing, disobedient, disturbing influence, violent, rude and egocentric)” (Eysenck & Eysenck, 1985, p. 53).

There has since been extensive replication of this factor structure of psychopathology in childhood, distinguishing between internalizing problems, including inhibition, shyness, and anxiety related to introversion, and externalizing problems, including aggressive and acting-out problems related to extraversion (Achenbach & Edelbrock, 1978; Cicchetti & Toth, 1991). Results of these analyses, combined with evidence for stability of extraversion-introversion across long periods (see reviews by Bronson, 1972; Kagan, 1998; and Rothbart, 1989a), suggest that individual differences on extraversion-introversion may be basic to both a description of temperament and, in their extremes, to an individual’s likelihood of demonstrating particular kinds of behavior problems or psychopathology. Later, we describe some direct and indirect links between temperament, caregiving, and risk for psychopathology. First, however, we discuss the structure of temperament.

TEMPERAMENT DIMENSIONS IN DEVELOPMENT

Much of the early research and thinking in the field of temperament in childhood has relied on Thomas and Chess’s pioneering work in the New York Longitudinal Study (NYLS; A. Thomas & Chess, 1977; A. Thomas, Chess, Birch, Hertzig, & Korn, 1963). Dimensions of temperament identified by the NYLS included activity level, threshold, mood, rhythmicity, approach/withdrawal, intensity, adaptability, distractibility, and attention span/persistence. Chess and Thomas (1986; A. Thomas, Chess, & Birch, 1968) also developed the important idea of “goodness of fit” to describe situations in which there is a “match” between the temperamental characteristics of the child and the expectations of others and/or demands of the situation. In their model, a good fit would predict a more favorable mental health outcome; a poor fit or incompatibility would predict impaired function and risk of development of behavior disorders.

In their case studies of children who survived an upbringing in multiproblem families with mental illness in one or more parents, Radke-Yarrow and Sherman (1990) identified two key protective factors. The first is very similar to Chess and Thomas's (1986) goodness-of-fit idea: "One key factor is a *match* between a psychological or physical *quality* in the child and a core *need* in one or both of the parents that the child fulfills" (Radke-Yarrow & Sherman, 1990, p. 112). The second, an extension of the first, is "the child's clear conception that there is something good and special about himself or herself. The child quality is then a source of positive self-regard for the child, as well as need-satisfying to the parent" (p. 112).

Child qualities providing a match or mismatch with parental need could be gender, appearance, intellectual or physical aptitude, or temperament. In American society generally, a positive and outgoing temperament may represent a particularly auspicious match between the child and many situational requirements; in school, effortful and/or fear control may provide a better match (Lerner, Nitz, Talwar, & Lerner, 1989). In other cultures, reserve rather than extraversion may be more generally valued (Chen, Rubin, & Li, 1995; Chen, Rubin, & Sun, 1992).

"Difficulty" in the New York Longitudinal Study Typology

A. Thomas, Chess, and associates (1963, 1968) also identified groups of children they designated as "easy," "difficult," and "slow to warm up," and their construct of "difficultness" has been frequently used in studies of the development of behavior problems. This construct stemmed from results of a factor analysis of data from the original NYLS, which identified a cluster of five temperament dimensions: approach/withdrawal, mood, intensity, adaptability, and rhythmicity, labeled as "difficult" (A. Thomas et al., 1963). In algorithms for assessing difficulty, developed by Carey and McDevitt (1978), Fullard, McDevitt, and Carey (1984), and others, difficulty is derived from extreme scores on all five dimensions.

There are several problems with the use of the difficulty construct in temperament research (for a discussion of this issue, see Plomin, 1982; Rothbart, 1982). One is the wide variability of operationalizations of the construct. Because factor analyses of data collected on the NYLS dimensions have frequently failed to yield loadings for rhythmicity in the difficulty factor (Bates, 1989), these studies often delete rhythmicity measurements or use varying composites, depending on the outcome of the factor analysis or the particular measures used in the study. Those based on the

Carey and McDevitt (1978) or Fullard et al. (1984) algorithms always include it. Inconsistency in the use of difficulty as a construct then creates serious problems for knowing what is meant by difficulty in any given study, and greater precision will result only when assessments of the construct are psychometrically sound and comparable across studies.

Bates (1980, 1989) argued that the core variable of measures of difficulty is negative emotionality, and his work used measures assessing this variable. Factor-analytic work by Bates and others also identified two kinds of negative emotionality in infancy: The first is related to children's responses to novelty and the second, more general distress proneness (Bates et al., 1979). Bates's research indicated that the two varieties of negative emotionality may be differentially related to specific behavior problems that develop later, and differentiated temperamental contributions to behavioral problems and psychopathology have consistently been found in recent research, as indicated later in this chapter and in Rothbart and Bates (in press). This differentiation is lost in the more general NYLS-based difficulty construct.

Another way of looking at difficulty is to say that some children are labeled by their caregivers as problem children at an early age, and this labeling is likely influenced by the child's temperament. Use of the terms "easy" and "difficult" may be further extended as a parent has more than one child ("The first was easy, but the second was difficult"). The terms may be applied in an endearing way or used to indicate the source of problems in family relationships. Attributions about the child may in turn contribute to developmental outcomes in the child's adaptation. Nevertheless, social attributions and values take us to a different level of analysis from measurement of temperamental dispositions in the child.

Revised Dimensions of Temperament in Infancy

In the original clinical application of the NYLS work (A. Thomas et al., 1968), no attempts were made to avoid conceptual overlap across the nine dimensions, so that individual questionnaire scales based on the NYLS have sometimes been highly overlapping in meaning. Findings of relatively high intercorrelations among scale scores designed to assess the NYLS dimensions have not been too surprising, given that a behavioral item might, in some cases, belong as easily to any one of three different scales (Rothbart & Mauro, 1990). Lack of internal homogeneity within individual scales based on some of the NYLS dimensions has also been found, which, when combined with

lack of independence among scales, has led researchers in Sweden and Australia to attempt item-level factor analysis of NYLS-based parent report scales (Hagekull & Bohlin, 1981; Sanson et al., 1987).

Results of item-level factor analysis in turn led to identification of a smaller number of factors that correspond well to dimensions of temperament derived from other developmentally based theoretical approaches to temperament (Buss & Plomin, 1975, 1984; Rothbart & Derryberry, 1981). These factors include distress and inhibition to novelty (including behavioral inhibition), other distress proneness or irritability, positive affect and approach, activity level, and persistence (Rothbart & Mauro, 1990).

Gartstein and Rothbart (2003) recently studied the factor structure of expanded scales measuring parent-reported infant temperament, adapted from dimensions identified in research on temperament in childhood. Factor analysis of a large data set describing 3- to 12-month-old children yielded three broad dimensions: *surgency/extraversion*, defined primarily from scales of approach, vocal reactivity, high-intensity pleasure (stimulation seeking), smiling and laughter, activity level and perceptual sensitivity; *negative affectivity*, with loadings from sadness, frustration, fear, and, loading negatively, falling reactivity; and *orienting/regulation*, with loadings from low-intensity pleasure, cuddliness, duration of orienting and soothability, and a secondary loading for smiling and laughter. As early as infancy, there is thus evidence for three broad temperament dimensions.

Dimensions of Temperament in Childhood

We have also developed a highly differentiated and comprehensive parent report instrument called the Children's Behavior Questionnaire, or CBQ (Rothbart, Ahadi, Hershey, & Fisher, 2001). Across a number of data sets using the CBQ, three temperament systems of surgency/extraversion, negative affectivity, and effortful control have emerged from research on temperament in children 3 to 7 years of age (Lonigan & Phillips, 2001; Rothbart, Ahadi, & Hershey, 1994; Rothbart et al., 2001). The surgency factor is primarily defined by scales assessing positive emotionality and approach, including positive anticipation, high-intensity pleasure (sensation seeking), activity level, impulsivity, smiling and laughter, and a negative loading from shyness. The negative affectivity factor involves positive loadings for shyness, discomfort, fear, anger/frustration, and sadness, and a negative loading from soothability-falling reactivity. The effortful control factor is defined by positive loadings from inhibitory control, attentional focusing, low-intensity pleas-

ure (non-risk-taking pleasure), and perceptual sensitivity. These broader factors suggest a hierarchical structure to temperament, with more narrow constructs related to each other at a higher level in the hierarchy. Questions regarding breadth of temperamental predictors of psychopathology are addressed later in the chapter.

The Big Five Factors of Personality and Temperament

These childhood temperament factors conceptually and empirically map fairly well on the extraversion/positive emotionality, neuroticism/negative emotionality, and conscientiousness/constraint dimensions found in Big Five studies of the adult personality (Ahadi & Rothbart, 1994; Rothbart, Ahadi, & Evans, 2000). These broad temperament constructs further suggest that temperament dimensions go beyond lists of unrelated traits and generalized characteristics of positive and negative emotionality. Particularly important are temperament-based interactions between the child's motivational impulses and his or her efforts to constrain them.

We (Ahadi & Rothbart, 1994; Rothbart, 1989d; Rothbart & Ahadi, 1994) and Martin and Presley (1991) have indicated possible relationships between temperament factors identified for childhood and personality factors identified for adults, and in our adult research program, we have found empirical links between negative affectivity and big five neuroticism, surgency/extraversion, and extraversion, and effortful control and conscientiousness (Evans & Rothbart, 2004; Rothbart, Ahadi, et al., 2000).

In the next section, we describe conceptual and neural models developed to enhance our understanding of these dimensions. The first two dimensions are positive affectivity and approach (surgency/extraversion) and fear (distress and latency to approach novel or challenging stimuli). The third dimension, anger/irritability, is seen, along with fear, discomfort, and sadness, to represent part of a general susceptibility to negative affect. These dimensions are particularly interesting because they are related to differences observed in nonhuman animals (Gosling & John, 1999; Panksepp, 1998) and to factor structures extracted from studies of personality in adults. The fourth dimension, effortful control, is further discussed in connection with a neural model for individual differences in alerting, orienting, and executive attention (Posner & Fan, in press). We begin our more specific discussion with a consideration of positive affectivity/approach and fear.

NEURAL MODELS

Cloninger (1986, 1987), Gray (1979, 1982), LeDoux (1987, 1989), Panksepp (1982, 1986a, 1998), and Zuckerman (1984) have all made contributions to the development of neural models for temperament (Rothbart, Derryberry, & Posner, 1994). LeDoux identifies emotions as broadly integrative systems ordering feeling, thought, and action. In his analysis, emotions are seen to be the output of information-processing networks assessing the meaning or affective significance of events for the individual (LeDoux, 1989). Whereas object recognition systems and spatial processing systems address the questions "What is it?" and "Where is it?," respectively, neural emotion-processing networks answer the questions "Is it good for me?" and "Is it bad for me?," in turn influencing the organism's behavioral answers to the questions "What shall I do about it?" or simply "What shall I do?"

In the neural processing of emotion, thalamic connections route information about object qualities of a stimulus through sensory pathways, while simultaneously routing information for evaluative analysis to the limbic system and the amygdala, where memories of the affective meaning of the stimulus further influence the process (LeDoux, 1989). Later stages of object processing update the emotional analysis based on early sensory information, but, in the meantime, back projections from the amygdala influence the subsequent sensory processing of the stimulus. Output of the amygdala to organized autonomic reactions via the hypothalamus and to motor activation via the corpus striatum constitutes the motivational aspect of the emotions.

In this view, emotional processing can be seen as information processing of a special sort. Attentional neural networks can then act on emotional information similarly to their action on output of other data-processing systems, including those for object recognition, language, and motor control, each of which in turn has its own underlying neural networks (Posner & Fan, *in press*; Posner & Petersen, 1990). Neuroimaging studies demonstrate connections between emotional processing networks and the anterior attention system, including the anterior cingulate, that allow attentional influence on the selection of emotional information for conscious processing, a consequence of which is that we may or may not be aware of our emotional evaluations (Bush, Luu, & Posner, 2000; Posner & Rothbart, 1992). However, the attentional controls on emotion may be somewhat limited and difficult to establish. Panksepp (1998, p. 319) lays out anatomical reasons why the regula-

tion of emotion may pose a difficult problem for the child as follows:

One can ask whether the downward cognitive controls or the upward emotional controls are stronger. If one looks at the question anatomically and neurochemically, the evidence seems overwhelming. The upward controls are more abundant and electrophysiologically more insistent: hence one might expect they would prevail if push came to shove. Of course, with the increasing influence of cortical functions as humans develop, along with the pressures for social conformity, the influences of the cognitive forces increase steadily during maturation. We can eventually experience emotions without sharing them with others. We can easily put on false faces, which can make the facial analysis of emotions in real-life situations a remarkably troublesome business.

Attentional systems can act on and influence conscious aspects of emotional analyses, and emotion also influences the focusing and shifting of attention (Derryberry & Reed, 1994, 1996; Gray, 1982). An important aspect of social adaptation involves the appropriateness of the person's social interaction and related acceptance by others (Parker & Asher, 1987). Information about the state of others is an important contributor to appropriate social action, and failure of access of this information to action and consciousness can be a critical element in the development of disordered functioning (Blair, Jones, Clark, & Smith, 1997). Focusing attention on threatening stimuli or on the self also may make access to information about others less accessible. These are important examples of information-processing aspects of temperament, with implications for social development and psychopathology.

Positive Affectivity and Approach

We now briefly consider neural models developed to describe a physical substrate for approach and inhibition. Based on animal research, Gray (1979, 1982) described the behavioral activation system (BAS), involving sensitivity to rewards, and the behavioral inhibition system (BIS), involving sensitivity to punishment, nonreward, novelty, and innate fear stimuli. These two systems are seen as mutually inhibitory, with their balance determining degrees of extraversion-introversion. Gray (1971, 1975) also posited a fight/flight system moderating unconditioned punishment. According to Gray's model of the BAS, reward-related projections from the amygdala to the nucleus accumbens activate the next step in a motor program that maximally

increases proximity to the desired stimulus. Converging dopaminergic projections to the accumbens enable the switch to this neuronal set, facilitating goal-oriented behavior (Gray, 1994; Gray & McNaughton, 1996).

In a broader behavioral facilitation system (BFS), Depue and Collins (1999) propose a circuit involving the nucleus accumbens, ventral pallidum, and dopaminergic neurons that codes the intensity of the rewarding stimuli, while related circuits involving the medial orbital cortex, amygdala, and hippocampus integrate the “salient incentive context.” Individual differences in the functioning of this network are thought to arise from functional variation in dopaminergic projections that encode the intensity of the incentive motivation and facilitate contextual processing across multiple limbic and frontal sites. As development proceeds, dopaminergic facilitation helps to stabilize synaptic contacts in the medial orbital and limbic circuits and thus to enhance responsivity to positive incentive stimuli (Depue & Collins, 1999).

Depue and Iacono (1989) originally posited the BFS to help account for Bipolar Affective Disorders. The BFS involves the individual’s initiation of locomotor activity, incentive-reward motivation, exploration of environmental novelty (if the stimulus and its context do not induce opposing fear reactions), and irritable aggression. In Depue and Iacono’s model, nucleus accumbens dopamine (DA) activity “appears to modulate the flow of motivational information from the limbic system to the motor system, and thereby contributes to the process of initiating locomotor activity, incentive, and goal-directed behavior” (p. 470). Panksepp (1982, 1986a, 1998) also reviewed the literature on DA effects, concluding that “the general function of DA activity in appetitive behavior is to promote the expression of motivational excitement and anticipatory eagerness—the heightened energization of animals searching for and expecting rewards” (1986a, p. 91). Cloninger (1986, 1987) specified a novelty-seeking dimension related to DA functioning, as did Zuckerman (1984) in his dimension of sensation seeking (see review by Rothbart, 1989b).

Tellegen’s (1985) factor-analytic research on personality in adults identified positive emotionality, a broad factor that includes positive affect and anticipation, and Watson and Clark (1997) have argued that there is a positive affect core to individual differences in extraversion. In research on infants (Rothbart, 1988; Rothbart, Derryberry, & Hershey, 2000), we have found expressions of positive affect (smiling and laughter) to be positively related to infants’ rapid latency to approach objects and to predict anticipatory eagerness about upcoming positive events when the same children were 7 years old.

In recent functional magnetic resonance imaging (fMRI) research, Canli et al. (2001) found that the brain’s activation to positive and negative pictures varied depending on the subject’s temperament or personality. Persons higher in extraversion showed greater brain response to positive than to negative stimuli in widespread frontal, temporal, and limbic activation of both hemispheres. Subjects higher in neuroticism reacted more to the negative than to the positive stimuli, and showed more circumscribed activation (frontotemporal) on the left side and deactivation in a right frontal area. These findings also demonstrated a positive emotional bias for extraverts and a negative bias for those high in neuroticism.

A quite different set of brain areas proved to be active in studies of persistence, a dimension of personality conceptually related to effortful control in temperament (Gusnard et al., 2003). The effects of persistence acted strongly on midline and lateral prefrontal areas that are quite different from those found active for positive and negative affect, suggesting regulatory aspects of persistence. An increasingly popular view is that effortful control (persistence) is represented in midline frontal areas and acts to regulate brain areas like the amygdala that are more clearly related to reactive aspects of negative affect (Posner & Rothbart, 2000).

Fear and Behavioral Inhibition

Factor analyses of infant temperament questionnaires have reliably yielded two distress factors: one involving distress to novelty, and the other, irritability, including distress to limitations or frustration (Rothbart & Mauro, 1990). In our recent revision of the Infant Behavior Questionnaire, we also found a higher-order negative emotionality factor that includes fear and frustration (Gartstein & Rothbart, 2003). The distress to novelty factor is linked to an extended latency to approach new objects (Rothbart, 1988), and a combination of behavioral inhibition and distress proneness to novelty appears to correspond to the introverted pole of a broader extraversion-introversion dimension.

Fear is an emotional response activated in the presence of threat or signals of upcoming danger, and its function appears to be a defensive one. Fear activation is accompanied by inhibition of ongoing motor programs and preparation of response systems controlling coping options such as fleeing, fighting, or hiding (see review by Rothbart, Derryberry, et al., 1994). In Gray’s (1991) model, the fear-related BIS is based on circuits that include the orbital frontal cortex, medial septal area, and the hippocampus. However, the amygdala has been more often identified as

the critical structure in the processing of conditioned fear (LeDoux, 1989).

Emotional networks involving the amygdala also appear to respond more strongly to novel than to familiar stimuli (Nishijo, Ono, & Nishino, 1988). Lesions of the amygdala in rodents disrupt autonomic and cortisol reactions, behavioral freezing, and fear vocalizations, and similar findings have been reported in primates (Lawrence & Calder, *in press*). In humans, functional neuroimaging studies by Calder, Lawrence, and Young (2001) and others support involvement of the amygdala in both acquiring and expressing fear, although not in the voluntary production of facial expressions of fear (A. K. Anderson & Phelps, 2002). The amygdala also is involved in the recognition of fear in the human face (Calder et al., 2001), and there is evidence in humans with amygdalar damage of reduced fear experience (Adolphs et al., 1999; Sprengelmeyer et al., 1999).

Projections from the amygdala implement autonomic and behavioral components of fear, including startle, motor inhibition, facial expression, and cardiovascular and respiratory change (Davis, Hitchcock, & Rosen, 1987). Individual variability in the structure and functioning of any of these subsystems may be related to variations in behavioral expressions of fear, and multiple components of other affective motivational systems such as approach/positive affect and anger/irritable distress would also be expected.

The amygdala also appears to affect information processing within the cortex. For example, the basolateral nucleus of the amygdala projects to frontal and cingulate regions involved in the executive attention system (Posner & Petersen, 1990), as well as to ventral occipital and temporal pathways involved in processing object information. These connections are consistent with the finding that anxious individuals show enhanced attention to threatening sources of information (e.g., Derryberry & Reed, 1994).

A psychobiological analysis of fear suggests that there may be less disagreement about temperament variables than had been previously thought. Fear includes components of arousal, felt emotion, motor response preparation for flight and/or attack (with responses often inhibited), and attention to the fear-inducing stimulus and/or possible escape routes (Davis et al., 1987). When temperament researchers study the construct, they sometimes stress its motivational aspects (e.g., A. Thomas & Chess's, 1977, approach/withdrawal; Kagan's, 1994, behavioral inhibition), its distress proneness aspects (Buss & Plomin's, 1975, emotionality; Goldsmith & Campos's, 1982, fear), its duration and susceptibility to interventions (Rothbart's, 1981, soothability),

its relation to arousal (Strelau's, 1983, reactivity), or multiple components of response (Rothbart & Derryberry's, 1981, fear). If we take the broader view of fear as suggested by the neuroscience analysis, however, agreement is more evident. Intercorrelations among scales measuring the differently named constructs further support this contention (Goldsmith, Rieser-Danner, & Briggs, 1991).

Differences in cerebral hemispheric activation have been related to temperamental tendencies toward approach versus inhibition-withdrawal. Evidence from electrophysiological (EEG) and lesion studies has related higher anterior left hemisphere activation in response to stimulation to increased positive affect and/or decreased negative affect (see reviews by Davidson et al., 2003; Davidson & Tomarken, 1989). The reverse relationships—higher anterior right hemisphere activation related to higher negative affect and/or decreased positive affect—have also been reported. Resting EEG asymmetries have also been related to positive and negative emotional reactivity (e.g., Davidson & Fox, 1989; Tomarken, Davidson, Wheeler, & Doss, 1992). Harmon-Jones and Allen (1997), for example, reported greater left than right-frontal cortical activity in women subjects with higher scores on Carver and White's (1994) BAS questionnaire. The BIS measure was not related to asymmetry. Buss et al. (2003) found relations between extreme right EEG asymmetry and basal and reactive cortisol, replicating primate findings from Kalin and his colleagues (Kalin, Larson, Shelton, & Davidson, 1998).

N. A. Fox, Calkins, and Bell (1994) found that infants with stable right frontal EEG asymmetry between 9 and 24 months of age displayed more fearfulness and inhibition in the laboratory than other children. At 4 years, children who showed more reticence and social withdrawal were also more likely to show right frontal asymmetry. Calkins, Fox, and Marshall (1996) reported that children selected for high motor activity and negative affect to laboratory stimulation at 4 months showed greater right frontal asymmetry at 9 months, mother reports of greater fear at 9 months, and more inhibited behavior at 14 months. However, no concurrent relation was found between behavior and frontal asymmetry at 9 and 14 months, and greater activation of both right and left frontal areas was related to higher inhibition scores at 14 months. Calkins et al. suggest a need to differentiate between fearful and angry distress, as discussed in the "Revised Dimensions of Temperament in Infancy" section. They also hypothesize that infant high motor/high negative affect and high motor/high positive affect may be associated with different kinds of problems developing later. For high motor/high positive affect, the problems would be associated with difficulties in control rather than inhibition.

Anger/Irritability and Aggressive Behavior

In Gray's (1991) model, a fight/flight system is constituted by circuits connecting the amygdala, ventromedial nucleus of the hypothalamus, central gray region of the midbrain, and somatic and motor effector nuclei of the lower brain stem, processing information involving unconditioned punishment and nonreward. When there is detection of painful or frustrating input, the brain stem effectors produce aggressive or defensive behavior. Panksepp (1982) discusses similar neural circuitry in terms of a "rage" system (see review by Rothbart, Derryberry, et al., 1994).

Important distinctions have more recently been made among different varieties of aggression and anger, in relation to their underlying neural systems. Aggression as a self-defense reaction seems to be based on the functioning of the same amygdala circuits as those involved in the production of fear (Blanchard & Takahashi, 1988). Aggression linked to protection of resources, competition, and offensive aggression, on the other hand, involves a different neural system based on the monoamine dopamine (Lawrence & Calder, in press). The DA system has been linked to both the production of offensive aggression (Smeets & González, 2000) and to the recognition of anger in the human face (Lawrence, Calder, McGowan, & Grasby, 2002). In Lawrence et al.'s study, DA blockade impaired the recognition of anger, whereas recognition of other emotions and of facial identity was spared.

Depue and Iacono (1989) suggest that the dopaminergic system may facilitate irritable aggression aimed at removing a frustrating obstacle, consistent with findings that DA agonists (e.g., amphetamine) can enhance aggressive behaviors. Their view suggests links between approach and frustration/anger, and, in fact, infants' and children's activity level and anger have been consistently positively related in parent-reported temperament (Rothbart & Derryberry, 2002). Moreover, infant activity level predicts not only positive emotionality at age 7 years, but also anger/frustration and low soothability-falling reactivity (Rothbart, Derryberry, et al., 2000). Together with findings relating 7-year surgency to aggression (Rothbart, Derryberry, et al., 2000), this suggests that strong approach tendencies may be linked to negative as well as positive emotions (Derryberry & Reed, 1994; Rothbart, Derryberry, et al., 2000). Children who quickly grasped objects during infancy showed 7-year high levels of positive anticipation and impulsivity, as well as high anger/frustration and aggression, again suggesting that strong approach tendencies can contribute to later specific negative emotions as well as to positive emotionality.

Negative Emotionality or General Distress Proneness

Negative emotionality or distress proneness is often viewed as a general dimension subsuming the emotions of fear, anticipatory anxiety, sadness, frustration/anger, guilt, and discomfort. For example, the Five-Factor model of adult personality includes negative emotions as components of the neuroticism superfactor. Neuroticism/negative emotionality has been found to be orthogonal to extraversion/positive emotionality (Eysenck & Eysenck, 1985; Tellegen, 1985; Watson, & Clark, 1992). As evident in our previous discussion, however, the positive relationship between anger/frustration and strong approach tendencies suggests that a more differentiated model is needed.

There are several possibilities for neural systems supporting higher-order negative emotion reactions. One is the link between systems supporting fear and self-defensive aggression (Blanchard & Takahashi, 1988). Defensive aggression in animal models seems to be based on the same amygdalar circuits as fear, and in humans, anger in response to threat may also be linked to fear. Negative affect systems are also regulated by more general neurochemical systems, including dopaminergic and serotonergic projections arising from the midbrain, and by circulating gonadal and corticosteroid hormones (Rothbart, Derryberry, et al., 1994; Zuckerman, 1995). Neurochemical influences may thus also provide coherence of emotional states in an individual and support more general factors of temperament such as negative emotionality.

For example, serotonergic projections from the midbrain raphe nuclei appear to moderate limbic circuits related to anxiety and aggression (Spoont, 1992). Low serotonergic activity may thus increase an individual's vulnerability to both fear and frustration, contributing to a general factor of negative affectivity, including depression. Molecular genetics studies related to serotonin function are therefore of interest in identifying negative affect as a general diathesis. Lesch et al. (1996), for example, have reported relations between a polymorphism of the serotonin transporter gene and measures of anxiety, depression, and neuroticism.

Affiliativeness/Agreeableness

We share with other animals, including mammals, birds, and fish, systems of affiliation that support pair bonds and care of the young (Insel, 2003). Panksepp (1986b) indicates that affiliative and prosocial behaviors may depend in part on opiate projections from higher limbic regions (e.g., amygdala, cingulate cortex) to the ventromedial hypothalamus, with brain opiates promoting social comfort and bonding,

and opiate withdrawal promoting irritability and aggressiveness. Because ventromedial hypothalamic lesions dramatically increase aggression, Panksepp also suggests that this brain region normally inhibits aggressive behaviors controlled by the midbrain's central gray area. Hypothalamic projections can allow for friendly, trusting, and helpful behaviors between members of a species by suppressing aggressive tendencies. Mechanisms underlying prosocial and aggressive behaviors would in this way be reciprocally related, in keeping with the bipolar agreeableness-hostility dimension found in Five Factor model of personality.

Panksepp (1993) has also reviewed research suggesting links between social bonding and the hypothalamic neuropeptide oxytocin (OXY), involved in maternal behavior, feelings of social acceptance and social bonding, and reduction of separation distress. OXY is also released during sexual activity by both females and males. In Cloninger's (1987) theory, *reward dependence* is a dimension ranging from being emotionally dependent, warmly sympathetic, sentimental, persistent, and sensitive to social cues to being socially detached, cool, tough-minded, and independently self-willed. He sees reward dependence as related to social motivation; it is thus similar to dimensions of affiliativeness or agreeableness.

Agreeableness, including at the high end the prosocial emotions and behaviors and affiliative tendencies, and at the low end aggression and manipulativeness, has been increasingly studied in childhood (Graziano, 1994; Graziano & Eisenberg, 1997; Graziano & Tobin, 2002). Like other originally bipolar dimensions, prosocial and antagonistic dispositions have been studied separately (Bohart & Stipek, 2001), and Graziano and Eisenberg (1997) suggest that the two dispositions may be separable, even though they are negatively related. In a related argument, Shiner and Caspi (2003) point out that antisocial and prosocial behaviors have different etiologies (Krueger, Hicks, & McGue, 2001). Any temperamental predisposition to prosocial behavior needs to be seen as an open system, interacting with social experience for its outcomes. In research linking parent-reported temperament to personality in early and middle childhood, two forms of extraversion/surgency have been identified; one is linked to prosocial behavior and the other to antisocial behavior and aggression (Rothbart & Victor, 2004), again suggesting the importance of socialization to the development of pro- or antisocial behavior.

Attentional Networks

Functional neuroimaging has allowed many cognitive tasks to be analyzed in terms of the brain areas they activate, and

studies of attention have been among the most examined (Corbetta & Shulman, 2002; Driver, Eimer, & Macaluso, in press; Posner & Fan, in press). Imaging data support the presence of three networks related to different aspects of attention. These networks carry out the functions of alerting, orienting, and executive control (Posner & Fan, in press). A summary of the anatomy and transmitters involved in the three networks is shown in Table 11.1.

Alerting is defined as achieving and maintaining a state of high sensitivity to incoming stimuli; orienting is the selection of information from sensory input; executive control involves the mechanisms for monitoring and resolving conflict among thoughts, feelings, and responses.

The alerting system has been associated with frontal and parietal regions of the right hemisphere. A particularly effective way to vary alertness has been to use warning signals prior to targets. The influence of warning signals on alertness is thought to be due to modulation of neural activity by the neurotransmitter norepinephrine (Marrocco & Davidson, 1998).

Orienting involves aligning attention with a source of sensory signals. This may be overt, as in eye movements, or may occur covertly, without any movement. Orienting to visual events has been associated with posterior brain areas, including the superior parietal lobe and temporal parietal junction and the frontal eye fields (Corbetta & Shulman, 2002). Orienting can be manipulated by presenting a directional or symbolic cue indicating where in space a person should attend, thereby directing attention to the cued location (Posner, 1980). Event-related fMRI studies have suggested that the superior parietal lobe is associated with orienting following the presentation of a symbolic cue (Corbetta & Shulman, 2002). The superior parietal lobe in humans is closely related to the lateral intraparietal area in monkeys, which is known to produce eye movements (R. A. Anderson, 1989). When a target occurs at an uncued location and attention has to be disengaged and moved to a new

TABLE 11.1 Brain Areas and Neuromodulators Involved in Attention Networks

Function	Structures	Modulator
Orient	Superior parietal	Acetylcholine
	Temporal parietal junction	
	Frontal eye fields	
	Superior colliculus	
Alert	Locus coeruleus	Norepinephrine
	Right frontal and parietal cortex	
Executive attention	Anterior cingulate	Dopamine
	Lateral ventral prefrontal	
	Basal ganglia	

location, there is activity in the temporal parietal junction (Corbetta & Shulman, 2002). Lesions of the parietal lobe and superior temporal lobe have been consistently related to difficulties in orienting (Karnath, Ferber, & Himmelbach, 2001).

The second major temperamental control system over reactive approach and action (the first is reactive fear) is effortful control, supported by development of the executive attention network. Executive control of attention is often studied by tasks that involve conflict, such as various versions of the Stroop task. In the Stroop task, subjects must respond to the color of ink (e.g., red) while ignoring the color word name (e.g., blue; Bush et al., 2000). Resolving conflict in the Stroop task activates midline frontal areas (anterior cingulate) and the lateral prefrontal cortex (Botwinick, Braver, Barch, Carter, & Cohen, 2001; Fan, Flombaum, McCandliss, Thomas, & Posner, 2003). There is also evidence for the activation of this network in tasks involving conflict between a central target and surrounding flankers that may be congruent or incongruent with the target (Botwinick et al., 2001; Fan, McCandliss, Sommer, Raz, & Posner, 2002). Experimental tasks may provide a means of fractionating the functional contributions of different areas within the executive attention network (MacDonald, Cohen, Stenger, & Carter, 2000).

Regulatory Functions of Attention

The anterior cingulate gyrus, one of the main nodes of the executive attention network, has been linked to a variety of specific functions in attention (Posner & Fan, in press), working memory (Duncan et al., 2000), emotion (Bush et al., 2000), pain (Rainville, Duncan, Price, Carrier, & Bushnell, 1997), and monitoring for conflict (Botwinick et al., 2001) and for error (Holroyd & Coles, 2002). These functions have been well documented, but no single rubric seems to explain all of them. In emotion studies, the cingulate is often seen as part of a network involving orbital frontal and limbic (amygdala) structures. The frontal areas seem to have an ability to interact with the limbic system (Davidson, Putnam, & Larson, 2000), which could fit well with the idea that attention subserves self-regulation.

A specific test of a self-regulatory role for the cingulate involves exposure to erotic films, with the requirement to regulate any resulting arousal. The cingulate activity shown by fMRI was found to increase in relation to the regulatory instruction (Beauregard, Levesque, & Bourgoulin, 2001). In a different study, cognitive reappraisal of photographs producing negative affect showed a positive correlation between the extent of cingulate activity and the amount of affect to be controlled (Ochsner, Bunge, Gross, & Gabrieli, 2002). Similarly, in a study in which hypno-

tism was used to control the perception of pain, cingulate activity reflected the degree of pain as rated by the subject under hypnosis rather than the physical intensity of the heat stimulus (Rainville et al., 1997). These results show a role for the anterior cingulate in regulating limbic activity related to emotion and provide evidence for its role as a part of a network involved in regulation, cognition, and affect (Bush et al., 2000).

In experimental paradigms like the Stroop and flanker tasks, conflict is introduced by the need to respond to one aspect of the stimulus while ignoring another (Bush et al., 2000; Fan, Flombaum, et al., 2003). Cognitive activity that involves this kind of conflict activates the dorsal anterior cingulate and lateral prefrontal cortex. Large lesions of the anterior cingulate either in adults (Damasio, 1994) or children (S. W. Anderson, Damasio, Tranel, & Damasio, 2000) result in great difficulty in regulating behavior, particularly in social situations. Smaller lesions may produce only a temporary inability to deal with conflict in cognitive tasks (Turken & Swick, 1999; Ochsner et al., 2002).

A major advantage of viewing attention in relation to self-regulation is that knowledge of the development of a specific neural network can be linked to the ability of children and adults to regulate their thoughts and feelings. Over the early years of life, regulation of emotion and behavior is a major issue of development, and issues of dysregulation continue to play a role in psychopathology in adults.

TEMPERAMENT AND ADAPTATION

Developmental studies of nondisordered children are consistent with models such as Gray and McNaughton's (1996), where an anxiety-related behavioral inhibition system inhibits an approach-related behavioral activation system. Fearful inhibition is well developed by the end of the 1st year of life, and if a disposition to behavioral inhibition is strong, expressive, approach and avoidance behavior will be moderated under novel or challenging situations. In nondisordered children, measures of infants' fearfulness in the laboratory negatively predict mothers' reports of children's impulsivity, activity, and aggression at age 7. Fearfulness in infancy also positively predicted susceptibility to guilt and shame, two powerful socializing emotions (Rothbart, Ahadi, et al., 1994; Rothbart, Derryberry, et al., 2000).

Approach, Frustration, and Aggression

Together with the earlier finding relating 7-year surgency to aggression (Rothbart, Derryberry, et al., 1994), this sug-

gests that strong approach tendencies may contribute to negative as well as positive emotionality (Derryberry & Reed, 1994; Rothbart, Derryberry, et al., 1994). Infants who showed strong approach in their short-latency grasps of objects at 6.5, 10, and 13.5 months showed high levels of positive anticipation and impulsivity, along with high anger/frustration and aggression at 7 years. This again suggests that strong approach tendencies contribute to later negative as well as positive emotionality.

Children showing rapid approach as infants also tended to be low in attentional and inhibitory control at age 7, and suggesting that strong approach tendencies may constrain the development of voluntary self-control. If approach tendencies are viewed as the “accelerator” toward action and inhibitory tendencies as the “brakes,” it is not surprising that stronger accelerative tendencies may weaken the braking influence of inhibitory control (Rothbart & Derryberry, 2002).

In our laboratory study, frustration at 6 and 10 months predicted 7-year anger/frustration but not fear, as well as other components of negative affectivity, including high discomfort, high guilt/shame, and low soothability (Rothbart, Derryberry, et al., 2000). Greater infant frustration in the laboratory was also related to higher 7-year activity level, positive anticipation, impulsivity, aggression, and high-intensity pleasure. Whereas infant fear is thus related to relatively weak approach behavior and to internalizing tendencies in childhood, infant frustration is related to stronger approach and to externalizing as well as internalizing tendencies. This finding is consistent with Panksepp’s (1998) suggestion that unsuccessful reward-related activities may activate the anger/frustration functions of a rage system. Strong approach tendencies may include positive expectations and frustrated reactions under conditions when those expectations are not met.

Fear, Aggression, and Over-Control

Fear appears to take on an important inhibitory role in early development, constraining approach and aggression, acting as a protective factor for the development of externalizing, and contributing to the development of conscience. In addition to Kochanska’s findings on fear and the development of conscience (reviewed by Rothbart & Bates, *in press*), children with concurrent Attention-Deficit/Hyperactivity Disorder (ADHD) and anxiety also show reduced impulsivity relative to children with ADHD alone (Pliszka, 1989), and aggressiveness appears to decrease between kindergarten and first grade in children who show internalizing patterns of behavior (Bates, Maslin, & Frankel, 1995).

From an evolutionary point of view, fearful inhibition can serve to protect the individual from approaching potentially harmful objects or situations. Nevertheless, the fearful form of inhibitory control remains a relatively reactive process that can be easily elicited by situational cues. In the course of development, this system can lead to rigid and overcontrolled patterns of behavior that can limit the individual’s positive experiences with the world (Block & Block, 1980; Kremen & Block, 1998).

Shiner and her colleagues have recently been studying the continuity of personality from the period 8 to 12 years to 20 years (Shiner, Masten, & Tellegen, 2002) and 30 years (Shiner, Masten, & Roberts, 2003). Tellegen’s self-report MPQ contains three broad personality factors. Positive emotionality (PEM) includes scales for well-being, achievement, social potency, and social closeness. Negative emotionality (NEM) includes scales for stress reaction, alienation, and aggression. Constraint (CON) includes scales for control, harm avoidance, and traditionalism. PEM was moderately predicted at age 20 by childhood mastery motivation, surgent engagement, and self-assurance in middle childhood (Shiner et al., 2002). PEM was also related to concurrent social and romantic competencies at 20 years, but not to any of the childhood measures of adaptation. NEM at 20, however, was related to childhood low adaptation in all areas and to all concurrent adaptation measures except romantic competence. Even controlling for childhood personality, lower academic achievement and greater conduct problems in childhood continued to predict adult NEM. Childhood mastery motivation and surgent engagement were inversely related to NEM in adulthood. At age 20, CON was predicted by earlier lower self-assurance and higher academic competence, but when childhood personality was controlled, it was not related to childhood adaptation.

Shiner et al. (2002) suggest on the basis of longitudinal findings that positive emotionality might be more closely linked to current adaptation, whereas negative emotionality shows more continuity with earlier adaptation. Later in the chapter, we note strong links between negative emotionality and psychopathology, both in childhood and adulthood. Negative emotionality is also particularly linked to behavior problems when effortful control is low (Eisenberg, Fabes, Guthrie, & Reiser, 2000). How might this occur? First, mental processing related to distress may have involved attempts to decrease distress, possibly including calling up repeated memories of the negative event. Positive experiences are likely to have been less rehearsed. Thus, when mental processing has been tied to difficult and painful situations in the past, one may face not only current problems, but also representations in memory of adaptations to events. Well-practiced associations make links between negative affect,

cognition, and action links stronger. Thus, early failure, such as poor achievement in school, may create the possibility of long-term negative affect that extends to a range of achievement situations later in life. Shiner et al. also found that adults high on negative emotionality were particularly upset by daily problems (Suls, Martin, & David, 1998).

Preschool Behavior and Adult Problems

Caspi et al. (2003) linked observations of 1,000 children at age 3 to their self-reported personality at age 26 (96% of the original sample). Undercontrolled children (10% of the sample) had been temperamentally impulsive, restless, distractible, and negativistic at age 3; confident children (28%) were friendly, eager, and somewhat impulsive; inhibited children (8%) were fearful, reticent, and easily upset; reserved children (15%) were timid but not extreme in shyness; well-adjusted children (40%) appeared to be capable of self-control, were adequately self-confident, and did not become upset during testing. At age 26, previously undercontrolled children were higher in negative emotionality, more alienated, and subject to stress reactions. They also tended to follow a traditional morality. Formerly inhibited and reserved children were high in harm avoidance, low in social potency (less vigorous, dynamic, forceful), and low in achievement. Both previously undercontrolled and confident children were low in harm avoidance. Confident children were high on social potency, whereas inhibited children were high in constraint and low in positive emotionality.

Caspi et al.'s (2003) findings provide evidence that the temperament of the child truly provides a core for the developing aspects of personality. Undercontrolled children, who combined extraversion/surgency, negative affect, and low attentional control at age 3, showed neurotic and alienated tendencies as adults. Confident extraverted children were confident and unfearful as adults. The more shy and fearful inhibited and reserved children maintained their caution and harm avoidance and were low in social potency, whereas the more extreme inhibited children were also high in constraint (a mixture of fearfulness and self-control) and low in positive emotionality and social support. The most interesting aspect of the results, however, go beyond temperament to touch on alienation, traditional values, and social support. Additional research on these topics is needed.

TEMPERAMENT, ATTENTION, AND PSYCHOPATHOLOGY

In this section, we discuss studies that have linked temperament and attention to the development of behavior

problems and other forms of psychopathology. Two concerns must be taken into account, however, in reviewing this literature. First, although studies have identified links between temperament and behavior problems or psychopathology, it is difficult to determine the direction of influence. Although temperament extremes may predispose a person to problems, an alternative interpretation is that the problems associated with the disorder lead to extremes in the behavior measured as temperament. For example, punishment from peers and teachers may lead to increased negative affect in the child. Asendorpf's (1989, 1990) model for the development of shyness follows two developmental routes: one is early appearing and related directly to temperament (social fearfulness); the other is indirect and operates through peer rejection and punishment. In the latter case, the child's shyness may have been not present initially but is shaped through social experience. In Asendorpf and van Aken's (1994) longitudinal research, only the latter form of shyness was related to the development of later problems in self-evaluation.

Another important issue raised by a number of investigators (e.g., Barron & Earls, 1984; Prior, Sanson, Oberklaid, & Northam, 1987; Sanson, Prior, & Kyrios, 1990; Wertlieb, Wiegel, Springer, & Feldstein, 1987), is the possible confounding of assessments of temperament and behavior problems, especially when they are assessed by the same rater (usually the mother). For example, items used to measure temperamental dimensions such as activity, approach/withdrawal, and adaptability may be very similar to items assessing behavior problems such as hyperactivity, anxiety, and oppositional behavior. Bates (1990), on the other hand, argued that if temperament contributes to the development of behavior problems, then conceptual overlap across constructs would be theoretically expected.

Lengua, West, and Sandler (1998) addressed possible contamination of measures by eliminating overlapping items between temperament and symptom measures; associations were nevertheless found between negative emotionality and depression, and between impulsivity and conduct problems in a large sample of children of divorce. In further support of Lengua et al.'s findings, Lemery, Essex, and Smider (2002) asked experts to categorize CBQ items (Rothbart et al., 2001) and behavior problem symptoms (Preschool Behavior Questionnaire; Behar & Stringfield, 1974) as temperament and/or behavior problem constructs. Factor analysis of longitudinal multi-informant combined data was also used. With the latter method, 9% of temperament and 23% of symptom items were confounded.

Removing all confounded items did not affect the extensive relation between the two measures, including mothers' reports of temperament predicting fathers' and caregivers'

reports of behavior problems. Temperament at 3 to 4 years also predicted later *Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV)* symptoms at age 5 (Lemery et al., 2002). Activity level, attentional focusing, and inhibitory control predicted ADHD better than internalizing or externalizing, but the general finding was that high negative emotionality and low effortful control predicted children's problems. Because the CBQ allowed further differentiation of the negative affectivity construct, anger was found to predict externalizing, whereas fear and shyness predicted internalizing problems.

Finally, Sheeber (1995; Sheeber & Johnson, 1994) used a treatment outcome study to address the overlap issue. In her research, parents were trained in a temperament-focused approach to parenting. In posttreatment assessment, differences were found for the trained parents in behavior problem ratings, but not temperament ratings. Children's behavior was reported as improved on both internalizing and externalizing measures. Although the temperament-focused content may have influenced this finding, Sheeber (1995) reviews another study with similar findings that used a behavior management program (Webster-Stratton & Eyberg, 1982).

Models and Research

Clark, Watson, and Mineka (1994) follow Tellegen (1985) in describing negative affectivity (NA) or neuroticism as a temperamental sensitivity to negative stimuli. Those high in NA

experience a broad range of negative moods, including not only fear/anxiety and sadness/depression but also such emotions as guilt, hostility, and self-dissatisfaction (Watson & Clark, 1984). A wide range of nonmood variables are related to this affective core, including negative cognitions (Clark, Beck, & Stewart, 1990), somatic complaints (Watson & Pennebaker, 1989), negativistic appraisals of self and others (Gara et al., 1993), diverse personality characteristics such as hardiness, pessimism, and low self-esteem, and various indices of job, marital and life dissatisfaction. (Clark et al., 1994, p. 104)

Watson, Clark, and Harkness (1994) also identify an affective core to positive affectivity or extraversion, ranging from "joyful, enthusiastic, energetic, friendly, bold, assertive, proud, and confident" to "dull, flat, disinterested, and unenthusiastic" (p. 106). In their review of the adult literature, including measures of negativity predating the onset of depression, Watson et al. concluded that temperamental negative affect is generally related to the mood disorders of both depression and anxiety, whereas low positive affect appears to be more specifically related to depression. In this case, two general temperamental dispo-

sitions would be seen as predispositions to depression, one to anxiety.

As noted earlier, externalizing disorders include aggression, overactivity, delinquency, ADHD, Conduct Disorder, and Antisocial Disorder (Achenbach & Edelbrock, 1978; Cicchetti & Toth, 1991). Using factor scores derived from *DSM-IV* items to assess these problems, scores based on hyperactivity-impulsivity, Conduct Disorder, and Oppositional Defiant Disorder are highly intercorrelated, and all three are highly correlated with attentional problems (Hartman et al., 2001). Internalizing problems include extreme shyness or inhibition, sensitivity, anxiety and depression. In Hartman et al.'s study of measures of child psychopathology based on the *DSM-IV*, anxiety and depression scores were highly intercorrelated, and both were correlated with attention problems. The temperamental characteristic most often linked to internalizing problems is negative emotionality, but links have also been made between low positive emotionality and depression and between the mood disorders and attentional control. Theoretical and empirical models are increasingly using both temperamental and environmental variables in predicting outcomes.

Differentiated Negative Emotionality and Behavior Disorders

We first consider studies in which differentiated measures of affect and self-regulation (effortful control) were used to predict both internalizing and externalizing behavior problems. In the Bloomington Longitudinal Study (BLS), infant and toddler Infant Characteristics Questionnaire (ICQ) temperamental difficultness (frequent and intense negative affect and attention demanding) predicted later externalizing and internalizing problems, as seen in the mother-child relationship, from the preschool to the middle-childhood periods (Bates & Bayles, 1988; Bates, Bayles, Bennett, Ridge, & Brown, 1991; Bates et al., 1985; Lee & Bates, 1985). Early negative reactivity to novel situations (unadaptability) predicted less consistently, but when it did, it predicted internalizing problems to a greater extent than externalizing problems. Early resistance to control (perhaps akin to the manageability dimension of Hagekull, 1989, and at least partly related to the construct of effortful control) predicted externalizing problems more than internalizing problems. This was also found in predicting externalizing problems at school in both the BLS and in a separate longitudinal study, the Child Development Project (CDP; Bates, Pettit, Dodge, & Ridge, 1998).

In a structural modeling analysis of CDP data dealing with the overlap in externalizing and internalizing symptoms, Keiley, Lofthouse, Bates, Dodge, and Pettit (2003) separated mother and teacher reports of 5 to 14 year olds'

behavior problems into pure externalizing, pure internalizing, and covarying scores, and then considered early childhood predictors of each of these scores. Resistant temperament (unmanageability) predicted the mother- and teacher-rated externalizing problems but not the internalizing ones. Unadaptable temperament (fear) their internalizing scores, and to a lesser degree, *negatively*, their externalizing scores. That is, fearful temperament predicted higher levels of internalizing problems and, less strongly, lower levels of externalizing problems. Finally, difficult temperament (negative emotionality and demand-iness) predicted neither of the pure scores but only the covarying externalizing plus internalizing score for mothers.

These predictions are all consistent with the models described at the beginning of this chapter where temperament extremes either constitute pathology dimensions or predispose to risk for these conditions. The linkages are of modest size, but they obtain from early in life. They are also not eliminated when family and parenting characteristics are included in prediction, so they are not simply artifacts of family functioning. Also supporting the general pattern, Gilliom and Shaw (2004) found, in a sample of preschool-age boys from low-income families, that high levels of negative emotionality were associated with initial levels of both externalizing and internalizing problems, whereas high levels of fearfulness were associated with high initial levels of internalizing problems and with increases in internalizing problems over time and with decreases in externalizing problems over time.

In the Dunedin longitudinal study (Caspi & Silva, 1995), ratings based on the child's behavior during testing sessions, aggregated from ages 3 and 5 years, predicted ratings of parents and teachers over ages 9 to 11 and in early adolescence (over ages 13 and 15). A temperament dimension combining lack of control, irritability, and distractibility predicted for both genders externalizing problems more strongly than internalizing problems or positive competencies. Early approach (positive responses to strangers and new test materials) predicted, inversely, internalizing problems better than externalizing problems for boys. It did not predict either kind of problem for girls. Early sluggishness (a factor combining a lack of positive affect, passivity, and wariness/withdrawal from novelty) predicted later internalizing and externalizing problems for girls, but not boys, as well as the relative absence of positive competencies for both girls and boys. The discovery of differentiated patterns in these studies has been found despite the tendency for externalizing and internalizing adjustment scores to be correlated with each other. Caspi and Silva report somewhat similar patterns of linkage between

early temperament and self-reported personality patterns on Tellegen's Multidimensional Personality Questionnaire, with undercontrolled children tending as adults to be low on harm/avoidance and high on social alienation, and inhibited children high on harm/avoidance, low on aggression, and low on social potency.

In a Swedish study, Hagekull (1994) found that parent-reported Emotionality, Activity, Sociability, Impulsivity (EASI) sociability/shyness aggregated over mothers' and fathers' questionnaires at 28 and 36 months predicted age 48-month aggregated parent ratings of internalizing problems. Early impulsivity also predicted later externalizing but not internalizing problems and lower ego strength. Early activity predicted later externalizing and, inversely, later internalizing. Negative emotionality predicted both kinds of behavior problems as well as lowered ego strength. This pattern of findings is consonant with the BLS and Dunedin studies.

Another group of studies considered relations between parent ratings on the Middle Childhood Temperament Inventory (Hegvik, McDevitt, & Carey, 1982) and adjustment. Wertlieb et al. (1987) found parent ratings of high negative mood to be correlated with both externalizing and internalizing disorders. Scales having to do with manageability (activity, nonadaptability, and intensity) and self-regulation (nonpersistence and nonpredictability), on the other hand, tended to have higher correlations with externalizing than with internalizing. Guerin, Gottfried, Oliver, and Thomas (1994) found a similar pattern of correlations between parent temperament reports and teacher adjustment reports at age 10 years, except that negative mood correlated more strongly with teacher reports of externalizing than internalizing behavior problems; similar relations were found between age 10 parent temperament ratings and age 11 teacher ratings. Teglasi and MacMahon (1990) found a similar pattern, with manageability and self-regulation temperament scales correlating more strongly with externalizing adjustment scales than with internalizing scales. In addition, their negative reaction to novelty scale was more closely associated with internalizing than externalizing scales, and mood was moderately to highly correlate with both kinds of adjustment.

McClowry et al. (1994) found parent-rated negative emotional reactivity to be related to both internalizing and externalizing problems, with low task persistence (self-regulation) correlated only with externalizing. Their approach scale did not correlate with either internalizing or externalizing. However, in research by Rothbart, Derryberry, et al. (2000), infant activity and smiling, related to extraversion, predicted 7-year aggressiveness and negativism; infant fear

predicted lower levels of aggressiveness and higher levels of fear, sadness, empathy, guilt, and shame.

Examining the link between temperament and behavior problems in older children (6- and 9-year-olds), Wertlieb et al. (1987) found high activity, withdrawal, distractibility, and intensity and low adaptability, persistence, negative mood, and unpredictability to be significantly related to higher behavior problem scores. Internalizing behavior scores (reflecting anxiety, phobias, social withdrawal, etc.) and externalizing behavior scores (reflecting hyperactivity, aggression, etc.) were also found to be differentially related to temperament. Withdrawal was more associated with internalizing scores, and high activity, distractibility, and low threshold more associated with externalizing scores.

Biederman et al. (1990), in a longitudinal cohort of highly inhibited and highly uninhibited children, found that inhibited children accounted for the majority of diagnoses of Anxiety Disorder (especially phobias) in their sample, and uninhibited children, the majority of the externalizing disorders (especially Oppositional Disorder). Despite the extreme sample, some extremely inhibited children later received attention deficit diagnoses, and some extremely uninhibited children received anxiety diagnoses, such as Overanxious Disorder. These results are similar to the more general pattern based on parent report studies and dimensional adjustment scores, in which there are some, if typically smaller, cross-domain correlations.

Rothbart, Ahadi, et al. (1994) considered relations between parent reports of temperament on the CBQ and adjustment on a newly developed questionnaire on social behavior patterns in a group of 6- and 7-year-olds. A second-order factor composite index of temperamental negative affectivity predicted the full range of social traits, including aggressiveness, guilt, help seeking, and negativity. However, components of the general negative affect factor were associated with the social traits in a more differentiated way: Fear and sadness were more related to traits such as empathy; anger and discomfort were more related to aggression and help seeking.

In summary, these findings indicate that fear-related negative affect is particularly related to internalizing disorders, and anger and irritability to externalizing disorders. In addition, although self-regulation is related to both internalizing and externalizing problems, it appears to be more strongly related to externalizing disorders. Fearful negative affect also appears to predict later lower externalizing problems, in keeping with its aspects as a control system. Thus, when negative affect is decomposed, there appear to be greater possibilities for differentiating the disposition to mood and behavior problems. Effortful con-

trol is also an important negative predictor of later problems. This control may serve both emotional and behavioral regulation. In the future, the uses of more highly differentiated measures of temperament are likely to lead to a better understanding of the development of adjustment and psychopathology.

Generality of Links with Negative Affectivity: Genetics Studies

Behavior genetics studies have also examined the generality of negative affect links to mood disorders, suggesting a general negative affect predisposition to anxiety and depression. The genetic correlation between anxiety and depression symptoms in adult twins is in the vicinity of 1.00, indicating shared genetic influence on these two disorders (Kendler, Heath, Martin, & Eaves, 1987). Given this overlap, Pennington (2002) suggests that more specific syndromes may be related to environmental events, with threat related to anxiety and loss to depression (Eley & Stevenson, 2000).

Considering again the model of temperamental extremes, predisposing to psychopathology, we might expect individual differences in fear or behavioral inhibition to be related to susceptibility to anxiety and a tendency toward social withdrawal. Wolfson, Fields, and Rose (1987) found that preschool children with Anxiety Disorders were reported by their mother to be less adaptable, more negative in mood, and more "difficult" than a nonanxious control group, and internalizing problems were related to high temperamental withdrawal. Rosenbaum et al. (1988) studied 2- to 7-year-old children of parents with Agoraphobia or Panic Disorder. Compared with children of psychiatric controls, the rates of behavioral inhibition were close to 80% for the children of the Agoraphobic or Panic Disorder parents, and approximately 15% for non-Major Depression controls. In a study of adult subjects with Major Depression, the codiagnosis of Agoraphobia or Panic Disorder has been found to be positively related to risk for psychiatric disorders in their children, especially risk for Major Depression and separation anxiety (Weissman, 1989). Weissman concluded that there may be a common underlying process constituting a vulnerability (diathesis) for both Panic Disorder and Major Depression. High comorbidity of anxiety and depression further suggest that differentiating the two is difficult, even at the level of clinical diagnosis (Kovacs & Devlin, 1998).

Imaging studies may cast further light on this question. K. M. Thomas et al. (2001) carried out an fMRI study on amygdala functions, comparing a small sample of children

with anxiety and Major Depression diagnoses in comparison with controls. Differential findings were reported for anxious and depressed children, with anxious children showing a stronger right amygdala response to fear faces and depressed children showed a decreased left amygdala response to all faces.

Kagan, Snidman, Zentner, and Peterson (1999) reported that highly reactive infants at 4 months were likely to be behaviorally inhibited at 4 years and to exhibit more anxious symptoms at age 7. Behavioral inhibition in toddlers also predicted general social anxiety at age 13, particularly for girls (Schwartz, Snidman, & Kagan, 1999). Recent genetics contributions to the fear/phobia literature suggest a continuum of diathesis, from fearfulness to phobias. In a twin study by Kendler, Myers, Prescott, and Neale (2001), the lifetime history of multiple phobias as well as irrational fears was assessed. For a sample of males, a common genetic factor was found for five phobia subtypes, as well as genetic factors specific to each subtype, and a common familial environmental factor. Kendler et al. also analyzed irrational fears, with findings consistent with the idea that the irrational fears were a mild manifestation of the same genetic risk factor that produced clinical phobias. A previous study of women subjects was in agreement with these findings for men (Kendler, Neal, Kessler, Heath, & Eaves, 1992).

Temperament and Environment Influences

Rubin and Burgess (2001) have reviewed research on links between temperamental behavioral inhibition, social withdrawal, and maladaptation. They distinguish, as did Rubin and Asendorpf (1993), between children who isolate themselves from the peer group (social withdrawal) and children who have been rejected by the peer group (social isolation). Their model posits that inhibited children withdraw from the peer group, thereby failing to develop social interaction skills, becoming increasingly uncomfortable among peers, and finally facing social isolation from the peer group. This experience, in turn, is expected to encourage negative self-perceptions with respect to social relationships and social competence. Rubin (1993) identified a group of 11-year-old children above the clinical cutoff on depression inventory scores. Compared with nondepressed 11-year-olds, the depressed children at age 7 had been high on social withdrawal and negative self-perception of social competence. The groups did not differ on 7-year-old aggression or popularity, suggesting that, contrary to expectation, the negative self-perception appeared to precede social isolation.

Rubin and Burgess (2001) suggest that relative right frontal EEG activation in inhibited children may be related to low left hemisphere-related affective regulation. They note Eisenberg, Shepard, Fabes, Murphy, and Guthrie's (1998) findings that early school-age children's shyness was related to distress, upset, and nervousness and negatively related to excitement and enthusiasm. Higher levels of negative emotions were also related to avoidant coping in social problem situations.

Finally, Rubin and Burgess (2001) review research indicating that mothers of anxious and avoidant children tend to direct, control, and protect their children. They note, however, that the influence could well be bidirectional, with children's apparent vulnerability leading to parental overprotection. It is worthy of note that several studies have now reported that anxious children whose mothers are more demanding and less protective show more favorable outcomes. For a more complete report of this work, see Rothbart and Bates (in press).

Bidirectionality brings up the model in which characteristics evoke reactions in others that can increase risk or buffer it. Bidirectionality can also apply to externalizing disorders such as Conduct Disorder, where parents are found to reject or punish their children. Studies where conduct-disordered boys interact with other mothers as well as their own find no differences between the two groups of mothers' commands and negative responses to the boys, influence on the adults' responses (K. E. Anderson, Lytton, & Romney, 1986). Given shared genetic endowment, both parents and children may also share biologically based temperamental dispositions. If parents also tend to be more fearful, for example, they may seek to control situations and to protect their children.

Studies have investigated the relationship of temperament to observations of naturalistic mother-child interaction in preschool-age children. Stevenson-Hinde and Simpson (1982) found that mothers reported effects of difficult-to-manage behavior on all relationships in the family, including interactions with siblings and mother-father interactions. In comparison to mothers of more manageable children, these mothers also reported higher levels of anxiety and irritability in themselves, many commenting that they "did not used to be like this." Rutter and Quinton (1984) reported that children showing negative mood, low regularity, low malleability, and fastidiousness were more likely to be the focus of depressed parents' criticism, hostility, and irritability. In Rutter's (1990, p. 191) terms, "The interactive process reflects a pattern in which the children's attributes make them a focus for the discord (thus increasing exposure to the risk variable) and increase

the probability that exposure will set in motion a train of adverse interactions that will prolong the risk.”

Lee and Bates (1985) observed mothers' interacting with 2-year-olds at home, where the mothers were trying to control their toddlers' "trouble" behavior. They found that more distress-prone ("difficult") children approached trouble more often, resisted their mothers' attempts to control them, and had mothers who were more likely both to use more aversive discipline and to give in to their children. Lee and Bates noted that these early interactions resembled the coercive cycle of behavior described in socially aggressive boys and their mothers (G. R. Patterson, 1977, 1980). Even at early ages, children who present their mother with more troublesome, resistant behavior may encourage their mothers to use aversive discipline tactics more frequently or to give in, and these in turn may be the antecedents of a coercive cycle of parent-child interactions related to problems with aggression (G. R. Patterson, 1980).

Activation and inhibition are both important in the development of children's conduct problems. G. R. Patterson (1980) reported that parents of nonaggressive problem children are effective in stopping their children's aversive behavior on three out of every four times they use punishment. When parents of aggressive problem children employ punishment, however, the likelihood that the child will persist in the problem behavior increases rather than decreases (G. R. Patterson, 1977, 1980; Snyder, 1977). In our laboratory, we have found (Hershey, 1992) that more aggressive (by mothers' report) 7-year-old children show less inhibitory control, that is, they respond more quickly after encountering an error message in a catch trial in an experimental task, than less aggressive 7-year-olds.

Extraversion and introversion may also be related to inhibitory control. Nichols and Newman (1966) asked subjects to view a visual pattern and match a subsequent pattern against it. Rewards and punishments were preprogrammed and noncontingent on subject response. On trials following punishment, introverts responded more slowly, but extraverts responded more *quickly*. Subjects who were more slowed by punishment performed better on the go/no go task (C. M. Patterson, Kosson, & Newman, 1987). In a study with young children, Saltz, Campbell, and Skotko (1983) found that, in support of Luria's (1961) observations, increasing the loudness of a "no go" command increased 3- to 4-year-old children's likelihood of performing a prohibited act. They also found that increasing loudness decreased the likelihood of responding for children 5 to 6 years of age, indicating developmental change in the excitatory and inhibitory control and their balance during the preschool years. Development of the executive at-

tention system underlying effortful control may be related to these findings.

In addition to their relationship to disinhibiting psychopathologies, positive, outgoing characteristics of the young child have been identified as a general *protective* factor for the development of risk factors and psychopathology. More active and outgoing children are likely to show fewer negative effects of institutionalization, possibly because they are more likely to receive greater attention from adult caregivers (Schaffer, 1966). Werner's (1986; Werner & Smith, 1982) longitudinal studies in Hawaii indicate that more positive affective and expressive characteristics in the young child from an at-risk population are associated with fewer psychosocial problems later in life. In addition, higher positive affect appears to be a negative predictor of problems with depression (Mineka, Watson, & Clark, 1998).

Effortful Control and Psychopathology

A second inhibitory influence on impulsivity in addition to fear or behavioral inhibition is the attentionally influenced capacity to withhold prohibited responses and activate prescribed ones, that is, effortful control. It has been suggested that this function may be divided into monitoring for conflict and executing inhibitory control (Botwinick et al., 2001). Monitoring for conflict has been related to anterior cingulate function, whereas lateral prefrontal areas may be more related to executing the inhibitory operation. In our 7-year-old sample, inhibitory control was predicted by infants' longer latency to approach toys at 11 and 13 months and by their lower activity level in the laboratory at 13 months (Rothbart, Derryberry, et al., 2000). At 7 years, inhibitory control was concurrently related to attentional control and empathy, and negatively to aggression. Inhibitory control was also moderately positively related to guilt/shame, although uncorrelated with behavioral inhibition as assessed in shyness.

Several components of effortful control have been identified in the development of behavior problems. Poor delay of gratification has been identified as a risk factor for aggressive and delinquent behaviors, and high delay of gratification to adaptive behaviors (Krueger, Caspi, Moffitt, White, & Stouthamer-Loeber, 1996). In clinic-referred children, Huey and Weisz (1997) found externalizing problems to be related to underregulation of behavior, and internalizing problems to high behavioral inhibition and low regulative resiliency. Eisenberg et al. (1996) reported correlations between teacher and parent ratings of low emotional and behavioral self-regulation and acting-out

behavior problems. Eisenberg, Guthrie, et al. (2000) directly predicted internalizing problems from low behavioral regulation and high negative emotionality, and found moderating effects of negative emotionality on the relation between low attentional regulation and externalizing problems in grade school children (only children high in emotionality showed the relation).

Eisenberg et al. (2001) compared the temperament of school-age children with externalizing problems to those with internalizing problems and nondisordered children. Children with externalizing problems showed higher anger and impulsivity and lower regulation. Eisenberg et al. (1998) also found, in nondisordered children, that high internalizing negative emotion at age 4 to 6 years predicted shyness at ages 6 to 8 and 8 to 10, but chiefly for children low in the ability to control attention shifting. Lack of emotional, behavioral, and attitudinal control in the preschool period, assessed via negativism, emotional lability, restlessness, and short attention span, has predicted externalizing behaviors in adolescents (Caspi, Henry, McGee, Moffitt, & Silva, 1995). In a multiple regression analysis, lack of control and low approach independently predicted boys' anxiety; lack of control and sluggishness were independent predictors for girls. Both lack of control and response to novelty (behavioral inhibition) predicted children's later problems with anxiety. Preschool lack of control has also been found to distinguish between life-course-persistent antisocial behavior and antisocial behavior limited primarily to the period of adolescence (Moffitt, Caspi, Dickson, Silva, & Stanton, 1996). There is also strong evidence of links between high levels of control and positive or adaptive outcomes (see review by Eisenberg, Fabes, Guthrie, & Reiser, 2002).

Merikangas, Swendsen, Preisig, and Chazan (1998) studied adults with psychiatric disorders and their 7- to 17-year-old children. Externalizing or substance use disorders in the offspring were associated with low attentional control and high activity across the life span. Anxiety and depression were associated with low adaptability and approach/withdrawal, and comorbidity of externalizing and internalizing disorders was associated with both clusters of temperament characteristics and with high clinical severity and impairment.

In a study of temperament, externalizing problems, and internalizing problems in older adolescents using the Attention Network Task (Fan et al., 2002), conflict performance on computerized measures of executive attention was related to mother-reported adolescents' self-regulation and negative affectivity (Ellis, 2002). Adolescents' perfor-

mance was related to teacher assessment of risk for developing antisocial behaviors. Executive attention scores, mother- and self-report self-regulation, and parental monitoring all contributed unique variance to the prediction of problem behavior scores, with individual difference variables accounting for relatively more variance than parenting variables. Mother- and self-reported self-regulation, self-reported affiliativeness and approach tendencies, and gender contributed to prediction of depressive mood scores. Parenting variables did not add significant variance to predicting depressive mood.

In summary, in addition to lack of inhibitory reactions to punishment (the BIS), lack of attentional or effortful control has been related to externalizing problems. We now consider how temperament may be related to family interaction that, in turn, can shape outcomes.

Additive Effects of Temperament and Parenting

In one model temperament and the caregiving environment make independent contributions to psychopathology outcomes, and often, temperament and parenting have shown additive contributions to behavior problems. Campbell (1991) reported results from two longitudinal samples. The first included 3-year-olds referred by parents; the second, a 3-year-old group rated by their teachers as inattentive, overactive, and impulsive, and a matched control group from the same class. Data were collected in home visits, laboratory, and preschool classrooms, and children in both samples have been followed longitudinally. There was consistency of ratings of externalizing behavior problems across parents and teachers of preschool, first-grade, and fourth-grade children, and relations were found between early inattention, hyperactivity, and the development of poor impulse control, and aggression and noncompliance. In addition, higher levels of externalizing problems in preschool children were found to be related to both higher levels of stress in the family and the mother's use of more negative control strategies. In support of this model, Keenan and Shaw (1994) found in a low-income sample that a composite of temperamental difficultness and resistance to control predicted laboratory measures of aggression in 18-month-old boys, but not girls.

By combining measures of temperament in the first 3 years, mothers' positive involvement (affection, teaching), and 3-year behavior problems, Bates and Bayles (1988) were able to predict both externalizing and internalizing behavior problems at 6 years. Fisher and Fagot (1992) also found that toddler temperament and parental discipline

practices were independently related to children's anti-social and coercive behavior at 5 to 7 years.

Interactive Effects

Another model involves interactive effects of temperament and parenting, and these also have been found. These are reviewed in Rothbart and Bates (in press), where recent contributions to the literature make this a particularly exciting area of research. For example, in the 1,500-subject Australian Temperament Study, infant difficult temperament had little direct relationship with 7- to 8-year-old hostile-aggressive problems, but when this temperament occurred in a setting reflecting poor mother-child relationships, the level of risk for behavior problems substantially increased (Swanson et al., 2000). Belsky, Hsieh, and Crnic (1998) also found that parenting of male infants was more predictive of externalizing behavior problems at 3 years for infants high in negativity versus those low in negativity.

Stice and Gonzales (1998) reported a moderating effect for temperament; maternal control and support were more strongly related to antisocial behavior among adolescents who were high on negative affectivity and behavioral undercontrol. Maziade et al. (1990) found that 7-year-old child difficulty in dysfunctional families with lack of parental rule clarity, consistency, and consensus predicted later oppositional and attention deficit disorders at 12 and 16 years. Few children with difficult temperament and a well-functioning family developed behavior disorders, and few of the very easy children at 7 showed problems at 12, regardless of family functioning.

Lengua, Wolchik, Sandler, and West (2000) found that both temperament (high positive emotionality, low negative emotionality, and impulsivity) and parenting (low rejection and inconsistent parenting) independently predicted successful adjustment after parental divorce. Interactive effects were found for dysfunction. Rejection was most strongly associated with behavior problems in children low in positive affect and inconsistency with problems for highly impulsive children. Belsky et al. (1998) found that parenting of male infants was more predictive of externalizing behavior problems at age 3 years for infants high in negativity. Shaw et al. (1998) regressed out main effects in predicting 24-month externalizing and found a remaining sex \times temperament \times parenting interaction. For boys, noncompliant temperament and mother rejection exerted independent effects on externalizing. For girls, noncompliant temperament predicted later behavior problems only when combined with mother rejection.

In a setting where negativity was not measured, Bates et al. (1998) found that 13- and 24-month-old children's resistance to control interacted with mothers' restrictive control at 6, 13 and 24 months to predict externalizing in middle childhood. For mothers who were low in control, negative correlations were found between earlier temperament and externalizing; when mothers were high in restrictive control, lower correlations were found. Bates et al. carried out a conceptual replication of this finding in a second study and suggested that resistance to control may reflect strong approach, weak fear, and/or low effortful control. Parental control may be more likely to lead to coercive cycles of interaction when the child is also highly negative, but when control is the main issue, children may actually benefit from mother's intervention.

Overall, these findings suggest that there are particular temperamental vulnerabilities that may make some children more susceptible than others to negative environments. In a recent study, Caspi et al. (2002) added an exciting molecular genetics contribution to this literature, looking specifically at the relation between child maltreatment and the child's possession of the MAOA gene, which has been related to the development of aggressivity in monkeys. Maltreatment was assessed between the ages of 3 and 11 years, and antisocial outcomes were predicted for male teenagers and adults. A significant gene-environment interaction was found, indicating that the effect of maltreatment was stronger in males with low MAOA activity.

This finding will require replication, but a link has also been reported between the same gene (MAOA) and the ability of normal subjects to regulate conflict in the Attention Network Test (Fossella, Posner, Fan, Swanson, & Pfaff, 2002). When people with two different alleles of the MAOA gene were studied in fMRI (Fan, Fossella, et al., 2003), a difference was observed in the amount of activity in the anterior cingulate, which is an important node in the executive attention network (Fan et al., 2002). MAOA is also linked to the regulation of norepinephrine, dopamine, and serotonin, 5-HT and thus appears to provide protection for antisocial outcomes given stressful early experience. The authors argue that studying other genotypes associated with stress responses may promote an understanding of "how stressful experiences are converted into antisocial behavior toward others in some, but not all, victims of maltreatment" (Caspi et al., 2002, p. 853).

In summary, evidence has increasingly been found for interactions between child temperament and caregiver treatment in psychopathology outcomes. In addition, studies continue to find additive contributions to temperament

and caregiver treatment in child outcomes. The coercion model suggests that child characteristics can influence parental reactions, leading to increased risk of externalizing psychopathology.

Gender Influences

With the exception of activity level (Eaton, 1994), sex differences are rarely found in early assessments of temperament (Rothbart, 1986), but behavior problems develop disproportionately in boys. Girls are at greater risk than boys for depression (Zahn-Waxler, Cole, & Barrett, 1991), and antisocial behavior is generally found at higher rates for males than for females (Eagly & Steffen, 1986). Research results currently describe interplay among temperament, social experience, and gender in the development of depressive mood; two studies suggest that antecedents for depressive mood may be somewhat gender-specific (Block, Gjerde, & Block, 1991; G. R. Patterson & Capaldi, 1990).

Measuring depressive mood at age 18, with self-reported anxiety partialled out, Block et al. (1991) found that girls' depressive mood was predicted from intro-punitive, oversocialized, and overcontrolling behavior at age 7 and from higher preschool IQ. Boys' depressive mood, on the other hand, was predicted from higher aggressive, self-aggrandizing, and undercontrolled behavior at age 7, and from lower preschool IQ. Variables assessing undercontrol for males and overcontrol for females were also found to be concurrently related to depressive mood at age 18 for this sample (Gjerde, Block, & Block, 1988). Block et al. noted that their findings were congruent with findings of a positive relationship between Conduct Disorder and depression for male but not for female clinically depressed preadolescents (Edelbrock & Achenbach, 1980; Puig-Antich, 1982).

G. R. Patterson and Capaldi (1990) provided further information on this point in research with two samples of fourth-grade boys. Their research results supported a model in which peer rejection is a central mediating influence on depressed mood. In this model, for at least some boys, undercontrolled behavior is seen to lead to peer rejection, which in turn is related to development of depressive mood. For girls, on the other hand, Zahn-Waxler et al. (1991) offered a developmental model for depression, highlighting vulnerability to depression in highly socialized girls. Once again, gender may be a moderating variable in the relation between temperament and the development of depressive mood.

In a further analysis of gender and psychopathology, Maziade, Cote, Bernier, Boutin, and Thivierge (1989) suggested that boys' "difficult" temperament is more stable

than girls' and that girls are prone to become less difficult over time even when there is stress in the family. In addition, Earls and Jung (1987) reported that marital discord and maternal depression are related to behavior problems in boys but not in girls. They speculated that boys may be under different socialization pressures than girls, especially when the mother is under stress, although the direction of effects might also be reversed, with boys' greater externalizing problems creating higher levels of stress for the mother and for her relationship with the father.

The reader will have noted the important links between failures of self-regulation and developmental disorders. In the final sections of our review, we consider what we have learned about attention systems in relation to the development of psychopathology.

ATTENTION AND PSYCHOPATHOLOGY

The ability of attention to regulate distress can be traced to early infancy (Harman, Rothbart, & Posner, 1997). In infants as young as 3 months, we have found that orienting to a visual stimulus provided by the experimenter produces powerful if only temporary soothing of distress. One of the major accomplishments of the first few years is for infants to develop the means to achieve this regulation on their own. These events have been reviewed in Rothbart and Rueda (2005) and Rothbart, Posner, and Kieras (in press).

A sign of the control of cognitive conflict is found late in the 1st year of life (A. Diamond, 1991). For example, in A-not-B tasks, children are trained to reach for a hidden object at location A, and then tested on their ability to search for the hidden object at a new location B. Children younger than 12 months tend to look in the previous location A, even though they see the object disappear behind location B. After the 1st year, children develop the ability to inhibit the prepotent response toward the trained location A and successfully reach for the new location B. During this period, infants develop the ability to resolve conflict between line of sight and line of reach when retrieving an object. At 9 months of age, line of sight dominates completely. If the open side of a box is not in line with the side in view, infants will withdraw their hand and reach directly along the line of sight, striking the closed side (A. Diamond, 1991). In contrast, 12-month-old infants can simultaneously look at a closed side while reaching through the open end to retrieve a toy.

The ability to use context to reduce conflict can be traced developmentally using the learning of sequences of locations. Infants as young as 4 months can learn to antici-

pate the location of a stimulus, provided the association in the sequence is unambiguous (Haith, Hazan, & Goodman, 1988). In unambiguous sequences, each location is invariably associated with another location (e.g., 123; Clohessy, Posner, & Rothbart, 2001). Because the location of the current target is fully determined by the preceding item, one type of information needs to be attended to, and there is therefore no conflict (e.g., location 3 always follows location 2). Adults can learn unambiguous sequences of spatial locations implicitly even when attention is distracted by a secondary task (Curran & Keele, 1993).

Ambiguous sequences (e.g., 1213) require attention to the current association in addition to the context in which the association occurs (e.g., location 1 may be followed by location 2 or by location 3). Ambiguous sequences pose conflict because for any association, there exists two strong candidates that can be disambiguated only by context. When distracted, adults are unable to learn ambiguous sequences of length six (e.g., 123213; Curran & Keele, 1993), a finding that demonstrates the need for higher-level attentional resources to resolve this conflict. In young children, even simple ambiguous associations (e.g., 1213) were not performed at above chance level until about 2 years of age (Clohessy et al., 2001).

Developmental changes in executive attention were found during the 3rd year of life using a conflict key-pressing task (spatial conflict; Gerardi-Caulton, 2000). Because children of this age do not read, location and identity, rather than word and ink color, served as the dimensions of conflict. Children sat in front of two response keys, one located to the child's left and one to the right. Each key displayed a picture, and on every trial a picture identical to one member of the pair appeared on either the left or right side of the screen. Children were rewarded for responding to the identity of the stimulus regardless of its spatial compatibility with the matching response key (Gerardi-Caulton, 2000). Reduced accuracy and slowed reaction times for spatially incompatible relative to spatially compatible trials reflect the effort required to resist the prepotent response and resolve conflict between these two competing dimensions. Performance on this task produces a clear interference effect in adults and activates the anterior cingulate (Fan, Flombaum, et al., 2003). Children 24 months of age tended to perseverate on a single response; 36-month-old children performed at high accuracy levels but, like adults, responded more slowly and with reduced accuracy to incompatible trials.

At 30 months, when toddlers were first able to successfully perform the spatial conflict task, we found that performance on this task was significantly correlated with

their ability to learn the ambiguous associations in the sequence learning task (Rothbart, Ellis, Rueda, & Posner, 2003). This finding, together with the failure of 4-month-olds to learn ambiguous sequences, holds out the promise of being able to trace the emergence of executive attention during the first months and years of life.

The importance of being able to study the emergence of executive attention is enhanced because cognitive measures of conflict resolution in these laboratory tasks have been linked to aspects of children's temperament. Signs of the development of executive attention by cognitive tasks relate to a temperament individual differences measure obtained from caregiver reports called effortful control. Children relatively less affected by spatial conflict received higher parental ratings of temperamental effortful control and higher scores on laboratory measures of inhibitory control (Gerardi-Caulton, 2000). We regard effortful control as reflecting the efficiency with which the executive attention network operates in naturalistic settings.

Assessing Individual Differences in Attentional Networks

The Attention Network Test (ANT) examines the efficiency of the three brain networks we have discussed (Fan et al., 2002). The ANT procedure uses differences in reaction times (RT) between conditions to measure the efficiency of each network. The procedure for the ANT is illustrated in Figure 11.1. Subtracting RTs obtained in the double-cue condition from RTs in the no-cue condition gives a measure of alerting due to a warning signal. Subtracting RTs to targets at the cued location (spatial cue) from trials using a central cue gives a measure of orienting. Subtracting RTs for congruent from incongruent target trials provides a measure of conflict and marks the executive attention network.

The ANT has some useful properties as a measure of attentional efficiency. It does not use language stimuli, so it can be used with children, speakers of any language, patients unable to read, or special populations. In about 20 minutes, the test provides a measure of the efficiency of the alerting, orienting, and conflict networks with reasonable reliability, in addition to overall RT and error rates. Measuring the three networks' scores in the same test also allows assessment of possible patterns of interactions between them. We do not exclude the possibility that certain psychopathologies or brain-injured patients would have a dysfunction in the way the attentional networks interact.

In a sample of 40 normal persons, network scores were reliable over two successive presentations. In addition, no

Figure 11.1 The figure illustrates the Attention Network Test (ANT). Each trial begins with one of the four cues shown in a. The three targets are shown in b. The time course of each trial is shown in c. At the bottom are the subtractions that provide the measurement of the efficiency of each network. Adapted from “Testing the Efficiency and Independence of Attentional Networks,” by J. Fan, B. D. McCandliss, T. Sommer, M. Raz, and M. I. Posner (April, 2002), *Journal of Cognitive Neuroscience*, 3, pp. 340–347. © 2002 by the Massachusetts Institute of Technology.

correlation was found among the three network scores. An analysis of RTs in this task showed large main effects for cuing and for the type of target, but only two small but significant interactions (Fan et al., 2002). They both involved very small reductions in conflict when either no warning cue is provided or when the cue is at the location of the target. The latter interaction is to be expected because the effective eccentricity of flankers is increased when attention is on the central arrow. The first finding appears to arise because with no warning, the subject is generally slow and some conflict resolution may occur during the longer overall RT. This effect also appears to be responsible for a small but significant negative correlation between alerting and conflict ($r = -.18$), found in a larger sample of more than 200 people who had taken the ANT (Fossella et al., 2002).

Recently, ANT scores have been used as a phenotype to assay the heritability of each of the attentional functions with a sample of 26 pairs of monozygotic and dizygotic twins (Fan, Wu, Fossella, & Posner, 2001). In accordance with their neuroanatomical and behavioral independence, the three attentional networks showed different heritability indexes. Despite the small scale of the study, the execu-

tive network scores showed a significant correlation ($r = .73$) between monozygotic twins. This correlation was also significant, although weaker, for the alerting scores ($r = .46$), while the orienting network showed no evidence of heritability.

A child version of the ANT has been developed that is appropriate for children from about 4 years of age. In previous work, we found that children work best when there is a story and when there is clear feedback on their performance (Berger, Jones, Rothbart, & Posner, 2000). In the child version of the ANT, five colorful fish replaced the arrows that typically appear in the flanker task. Children are invited to help the experimenter feed the middle fish by pressing a button corresponding to the direction in which it is swimming. Visual feedback (the middle fish smiles and bubbles come out of its mouth) and auditory feedback (a “woohoo” sound) is provided when the response has been successful. In each trial, the flanker fish are swimming in the same (congruent) or opposite (incongruent) direction as the center fish.

Using the child ANT, the developmental course of the attentional networks has been studied (Rueda, Fan, et al., 2004; Rueda, Posner, & Rothbart, 2004). As in the adult data, the child study revealed independence among the three network scores. Despite a common decline in RT, each network also showed a different developmental course. Significant improvement in conflict resolution was found up until age 7 as compared to younger children, but a remarkable stability in both RT and accuracy conflict scores from the age of 7 to adulthood. Alerting scores showed some improvement in late childhood and continued development between 10 years old and adulthood. Finally, the orienting score at the age of 6 was similar to adult levels. The normal development of these networks may be important in understanding issues related to developmental pathologies such as those in Autism, ADHD, and anxiety and depression.

DEVELOPMENT AND ATTENTIONAL PATHOLOGIES

Attention is a very frequent symptom of many forms of psychopathology. However, without a real understanding of the neural substrates of attention, this has been a somewhat empty classification. This situation changed with the systematic application of our understanding of attentional networks to pathological issues. Viewing attention in terms of underlying neural networks provides a means of classifying disorders that differs from the usual internalizing versus externalizing classification that we applied earlier in the

chapter. A number of abnormalities involving attention, including Alzheimer's dementia, anxiety, ADHD, Autism, Borderline Personality Disorder, depression, and Schizophrenia, have been studied either with the ANT (Fan et al., 2002), which measures the efficiency of all three networks (see Figure 11.1), or parts of the task that measure one or two of the networks.

Alerting

The alerting network is obtained in the ANT by subtracting RTs following a warning of when a target will occur from RTs when participants do not receive any warning signal. Alerting shows the longest period of development of any of the networks, not reaching adult levels even by age 10 (Rueda, Fan, et al., 2004). Young participants have larger alerting scores than adults because they have abnormally long RTs without a warning signal. These effects are reduced with age. One effect of a warning signal is to improve the alert state, but there may be other influences as well. For example, children may rehearse the task after the warning signal, and this may allow them to respond more quickly, and they may be caught somewhat unawares when a target occurs without warning. Because the ANT is so simple, adults don't seem to need to rehearse during the warning interval once the task has been well learned.

It is also known that patients with anterior and posterior right hemisphere damage have problems when tasks are given without warning (Posner, Inhoff, Friedrich, & Cohen, 1987; Robertson, Mattingley, Rorden, & Driver, 1998). This arises because patients, like young children, have very long RTs in the absence of warning. Robertson has argued that the inability to maintain the alert state without a warning signal is a major contributor to the reduced attention to the side of space opposite the lesion, found more strongly in patients with right than with left posterior lesions.

A study using the ANT has shown that normal elderly persons also show dramatically larger alerting effects than young adults, resembling what is found with children (Fernandez-Duque & Black, in press). The study also found that normally developing older adults and Alzheimer's patients showed the same elevated alerting scores, but only the Alzheimer's patients showed increased difficulty in resolving conflict (see also our later discussion of executive attention).

Attention-Deficit/Hyperactivity Disorder

Studies of ADHD have linked the disorder to aspects of both attention and sensation seeking, a component of extraversion/surgency (Swanson et al., 2001). Many theories of

ADHD have also suggested a deficit in executive functions (Barkley, 1997). However, in early work using a spatial orienting task, the most compelling deficit appeared to be a difficulty in maintaining the alert state in the absence of a warning signal (Swanson et al., 1991). This difficulty might arise from right hemisphere damage, which has also been reported to be a feature in many studies of ADHD.

More recent studies using the ANT have replicated problems with alerting in ADHD, again mostly due to the inability to maintain the alert state when no warning signal was used (Beane & Marrocco, 2004; Booth, Carlson, & Tucker, 2001). In one of these studies (Booth et al., 2001), the ANT was used to discriminate the Inattentive subtype from normal children and the Combined subtype. The alerting network best distinguished the different forms of ADHD, with Inattentive children showing less ability to maintain the alert state in the absence of warning signals. Neuroimaging studies of ADHD children have generally shown right frontal, cingulate, and basal ganglia deficits (Casey et al., 1997). Because right frontal areas have been related both to problems with the alert state and with inhibitory control, there could be links between the ANT results and these imaging studies, but this research has not yet been done.

Casey, Durston, and Fossella (2001) used three different tasks that rely on different processes (stimulus selection, response selection, and response execution) to analyze executive functions in different types of developmental disorders (Schizophrenia, Sydenham's chorea, Tourette's syndrome, and ADHD). They suggest that each of the cognitive operations is implemented in a particular basal ganglia-thalamocortical circuit. Stimulus processing seems to be related to connections among basal ganglia, thalamus, and the dorsolateral prefrontal cortex, whereas response processing is associated with connections of subcortical structures to the lateral orbital frontal cortex. Schizophrenic patients exhibited deficits in stimulus selection, Sydenham's chorea patients in response selection, Tourette's syndrome children in response execution, and ADHD children in both stimulus selection and response execution, suggesting that specific cognitive operations related to executive attention can be independently damaged.

For a number of years it has been thought that ADHD related to problems with dopamine and other catecholamine function (Wender, 1971). In molecular genetics research, the dopamine theory found support in replicated findings that one allele (the 7-repeat) of the dopamine 4 receptor gene is overrepresented in children with ADHD and also is associated with a temperament featuring high sensation seeking (see Swanson et al., 2001, for a recent summary). Sensation

seeking is a lower-order construct of extraversion. This finding has been well replicated for the syndrome of ADHD, but the allele has not been associated with a cognitive deficit in executive function in a study of children with and without the 7-repeat allele (Swanson et al., 2000). The 7-repeat was associated with ADHD but not with the cognitive deficit that usually accompanies ADHD (Swanson et al., 2000). This finding led to the suggestion that there may be two routes to ADHD. One would involve a temperamental extreme of sensation seeking (or extraversion), the frequency of which might be increased by the presence of the repeat version of the dopamine 4 receptor gene. This route need not involve a cognitive deficit. A second route to ADHD would involve cognitive deficits that might be either genetic or due to early brain injury or other experiential factors.

Orienting

Orienting network efficiency is obtained from the ANT by subtracting the spatial cue RTs from the center cue RTs.

Anxiety and Depression

There is much new information on the role of attention in anxiety, depression, and mood disorders. In a series of studies, subclinical college students with high scores on trait anxiety were cued to attend to a location by a positive, negative, or neutral face. Trials on which the cue to the location was negative and invalid produced longer reaction times for the trait anxiety subjects (E. Fox, Ricardo, & Dutton, 2002; E. Fox, Russo, Bowles, & Dutton, 2001). These results replicate and extend previous studies by Derryberry and Reed (1994) and together suggest that trait anxiety influences the ability to disengage, particularly from threat stimuli. Derryberry and Reed suggest that this finding may be dependent on relatively low levels of effortful control. Subjects high in effortful control but suffering from depression did not have difficulty disengaging from negative affect.

A symptom of depression is the tendency to dwell on negative ideation (Beck, 1976). Vasey and Macleod (2001) reviewed recent studies on trait-anxious children, finding evidence of their making threatening interpretations of ambiguous stimulus material, overestimating the likelihood of future negative events, and showing a negative bias toward threatening information. Negative bias has also been noted in children's speeded detection of dot probes in the vicinity of threatening words (Bijttebier, 1998; Schippel, Vasey, Cravens-Brown, & Bretveld, 2003). In temperament research, the ability to control attention was found to be neg-

atively related to negative affect (Derryberry & Rothbart, 1988; Rothbart, Ahadi, et al., 2000), congruent with the interpretation that good attentional mechanisms may serve to protect against negative ideation.

Children with a history of abuse have also been found to be hypersensitive to the recognition of angry faces, misclassifying objectively neutral faces as angry (Pollak & Kistler, 2002). Together, these findings suggest that both temperament and experience can influence aspects of attention toward threat stimuli, perhaps by both enlarging the boundary of the classification and increasing the time to dwell on these stimuli. Because orienting to cues and targets can be studied in children from birth onward (Pollak & Kistler, 2002), it is possible to use these findings to obtain more information on the effect of anxiety on normal development and to determine the degree to which it predicts later problems given stressful experience.

Brain systems related to unipolar depression have been explored in a number of imaging studies (Drevets & Raichle, 1998; Liotti, Maybert, McGinnis, Brannan, & Jerabeck, 2003). These studies have generally shown the importance of midline frontal areas, including the anterior cingulate and orbital prefrontal cortex. In normal persons, these areas are related to the experience and control of emotion (Bush et al., 2000), behavior and cognition (Drevets, 2000), and self-image (Gusnard et al., 2003). The areas appear to function abnormally in depressed persons exposed to material producing a sad mood, whether or not they were currently depressed. The overlap between brain activities in currently depressed people with those who have suffered from depression in the past may explain the frequent occurrence of multiple depressive bouts.

Autism

Autism is a disorder that has been linked to the orienting system (Akshoomoff, Pierce, & Courchesne, 2002; Landry & Bryson, 2004; Rodier, 2002). It is well-known that autistic persons do not normally orient to faces. However, Landry and Bryson (2004) report autistic difficulty in orienting in tasks that involve nonsocial stimuli similar to those used in the ANT. Similar deficits in the ability to disengage and move attention have been reported in Autism in relation to abnormal development of the cerebellum (Akshoomoff et al., 2002). We do not know if this abnormality is due only to cerebellar deficits, as many of the patients also show parietal abnormalities as well (Allen & Courchesne, 2001). Moreover, the pattern of advantages and difficulties in orienting displayed by autistic persons (summarized in Allen & Courchesne, 2001) suggest that the core difficulty may lie in executive control of orienting

rather than being a result of simply parietal or cerebellar deficit. These results may serve to related the orienting difficulties in Autism to higher-level executive deficits (Frith, 2001). Rodier has some evidence that the orienting abnormalities found in Autism might relate to a gene associated with migration of cells in early development.

Executive Function

Executive network efficiency in the ANT is obtained by subtracting the congruent trial RTs from the incongruent trial RTs.

Borderline Personality Disorder

Borderline Personality Disorder is characterized by very great lability of affect and problems in interpersonal relations. In some cases, patients are suicidal or carry out self-mutilation. Because this diagnosis has been studied largely by psychoanalysts and has a very complex definition, it might at first be thought of as a poor candidate for a specific pathophysiology involving attentional networks. However, we focused on the temperamentally based core symptoms of negative emotionality and difficulty in self-regulation (Posner et al., 2002). We found that patients were very high in negative affect and relatively low in effortful control (Rothbart, Ahadi, et al., 2000), and defined a temperamentally matched control group of normal persons without personality disorder who were equivalent in scores on these two dimensions. Our study with the ANT found a deficit specific to the executive attention network in borderline patients (Posner et al., 2002). Preliminary imaging results suggested overgeneralization of responding in the amygdala and reduced responding in the anterior cingulate and related midline frontal areas (Posner et al., 2002). Patients with higher effortful control and lower conflict scores on the ANT were also the most likely to show the effects of therapy. This methodology shows the utility of focusing on the core deficits of patients, defining appropriate control groups based on matched temperament, and using specific attentional tests to help determine how to conduct imaging studies.

Schizophrenia

A number of years ago, never-medicated schizophrenic patients were tested both by imaging and with a cued detection task similar to the orienting part of the ANT. At rest, these subjects showed a focal decrease in cerebral blood flow in the left globus pallidus (Early, Posner, Reiman, & Raichle, 1989), a part of the basal ganglia with close ties to the anterior cingulate. These subjects showed a deficit in orienting similar to what had been found for left parietal

patients (Early et al., 1989). When their visual attention was engaged, they had difficulty shifting attention to the right visual field. However, they also showed deficits in conflict tasks, particularly when they had to rely on a language cue. It was concluded that the overall pattern of their behavior was most consistent with a deficit in the anterior cingulate and basal ganglia, parts of a frontally based executive attention system.

The deficit in orienting rightward has been replicated in first-break schizophrenics, but it does not seem to be true later in the disorder (Maruff, Currie, Hay, McArthur-Jackson, & Malone, 1995), nor does the pattern appear to be part of the genetic predisposition for Schizophrenia (Pardo et al., 2000). First-break schizophrenic subjects often have been shown to have left hemisphere deficits, and there have been many reports of anterior cingulate and basal ganglia deficits in patients with Schizophrenia (Benes, 1999). The anterior cingulate may be part of a much larger network of frontal and temporal structures that operate abnormally in Schizophrenia (Benes, 1999).

A recent study using the ANT casts some light on these results (Wang et al., in press). In this case, the schizophrenic patients were chronic and were compared with a similarly aged control group. The schizophrenic patients had much greater difficulty resolving conflict than did the normal controls. The deficit in patients was also much larger than that found for borderline personality patients. There was still a great deal of overlap between the patients and normal subjects, however, indicating that the deficit is not suitable for making a differential diagnosis. The data showed a much smaller orienting deficit of the type that had been reported previously. These findings suggest that there is a strong executive deficit in chronic Schizophrenia, as would be anticipated by Benes's (1999) theory. It remains to be determined whether this deficit exists prior to the initial symptoms or develops with the disorder.

Chromosome 22q11.2 Deletion Syndrome

This is a complex syndrome that involves a number of abnormalities, including facial and heart structure but also a mental retardation to deletion of a number of genes. Children with the deletion are at high risk for developing Schizophrenia. Among the genes deleted in this syndrome is the COMT gene, which has been associated with performance in a conflict task (A. Diamond, Briand, Fossella, & Gehlbach, 2004) and with Schizophrenia (Egan et al., 2003). In light of these findings, it was to be expected that the disorder would produce a large executive deficit (Simon et al., in press; Sobin et al., 2004). Sobin has reported in another paper (Sobin, Kiley-Bradeck, & Karayiorgou, 2005)

that the deficit in resolving conflict is associated with the ability to inhibit a blink following a cue that a loud noise would be presented shortly (prepulse inhibition). The authors indicate that the association of the high-level attention and prepulse inhibition deficit suggests a pathway that includes both the basal ganglia and the anterior cingulate.

Summary

Many neurological and psychiatric disorders produce difficulty in attention. Data to date suggest that disorders have specific influences on attentional networks. However, a number of disorders influence the same network (e.g., Schizophrenia, Borderline Personality Disorder, and Alzheimer's dementia affect executive attention), and the same disorder can influence more than one network (e.g., Schizophrenia may affect both the executive and orienting network, although perhaps at different stages of the disorder). These findings reduce the utility of attention as a means of classifying disorders, but they may be useful in understanding their etiology and suggesting methods of treatment, at least of the attentional symptoms.

SUMMARY AND FUTURE DIRECTIONS

In this chapter, we described recent findings on the structure and development of temperament and related temperament and attention to the development of psychopathology. We noted that temperament involves a number of interacting systems, each of which follows its own course of development. We identified two major control systems of temperament, reactive fearfulness and self-regulatory effortful control, with the latter based on the development of executive attention that serves to moderate or break the approach and incentive-related systems and allow activation of lower probability responses.

We described a hierarchical structure of temperament. General negative affectivity includes dispositions toward fear, frustration/anger, sadness, and discomfort, as well as low soothability. General surgency, or extraversion, includes impulsivity, high-intensity pleasure, activity, and sociability. Effortful control includes inhibitory control, low-intensity pleasure, attentional shifting and attentional focusing. These three higher-order general dimensions of temperament are related to three of the Big Five factors, as well as the Big Three factors in adult personality.

As suggested by Cicchetti and Cohen (1995), there are multiple routes to psychopathology, as well as to positive adaptation, and the influence of a given temperamental

characteristic may vary depending on other temperamental or contextual influences. The nature of the person's experiences and the choice of settings will also be influenced by affect and regulated by attention. Although experiences may be chosen on the basis of their affective consequences, they may also be influenced by the planning processes that are part of temperamental effortful control.

Temperamental factors may predispose children and adults to psychopathological outcomes and contribute to the maintenance, reduction, or intensification of an outcome. In addition, a given temperamental characteristic may predispose to more than one psychopathology outcome. Temperament is related to both risk and protective factors in the development of psychopathology; it may influence risk of recurrence of the disorder and may bias information processing about the self, leading to further risk or protective factors for the development of psychopathology. In addition, experience, including the experience of disorder, will affect the range of stimuli activating the temperamental response and the intensity and regulation of the reaction.

Temperament involves constitutional differences in reactivity and self-regulation. In this chapter, we were able to make connections between disorders and attentional networks. These connections are possible due to the increasing use of brain imaging studies of common aspects of brain networks and of individual differences. Temperamental differences in extraversion, negative affect, and persistence tasks can provide clues for understanding the genes responsible for the relatively high heritability of temperament scales. We expect the search for brain mechanisms underlying temperament and for candidate genes involved in producing these effects to be a major topic of research in the future.

The ability of temperamental differences to predict disorders has been impressive, but it is not yet possible to determine the direction of these effects. Increased understanding of the brain networks and genetic mechanisms related to temperamental dimensions could improve this picture and allow us to understand which aspects of temperament predictions of disorders are causative. A large number of disorders have now been shown to produce different specific effects on attention networks. Although these effects might not be reliable enough to be used as differential diagnoses, they do provide clues to the anatomy impaired by the disorder and in the future may guide more specific therapeutic strategies.

When we wrote this chapter for the first edition of the *Handbook*, we speculated on possible relations between temperament and psychopathology and on brain systems

related to reactivity and self-regulation. Evidence for these connections has vastly improved in the 8 intervening years. We expect by the time the *Handbook* is again rewritten, these trends will be even more developed, and we hope that they will lead to both better understanding and more certain improvements in treatment.

SUMMARY AND CONCLUSIONS 527

REFERENCES 528

For most of its history, psychology has emphasized external forces that arise from the environment to shape human personality. This view began during the behaviorist era, when learned connections between external stimuli and responses were viewed as central. It has continued during the cognitive era, though the emphasis has, of course, shifted from the external world to representations of the environment. This general environmental paradigm in psychology has provided many useful constructs for understanding psychopathology and its development. We now have a number of models through which external environments, internal representations, and adaptive or maladaptive behaviors can be linked (Beck & Clark, 1997; M. W. Eysenck, 1997; Wells & Matthews, 1994).

Nevertheless, the recent advent of neuroscience research has provided an additional perspective for viewing human personality, one that emphasizes internal biological processes along with external events and their representations (Cicchetti & Tucker, 1994; Derryberry & Rothbart, 1997). Although in many instances, neuroscience data converge quite well with psychological constructs, in other instances, the biological perspective suggests that a much broader view is required than that provided by most psychological models. For example, we often think of an external stimulus as being processed within the cortex, as if the cor-

tex were some highly complex electronic computer. What we find, however, is that the information within the cortex is embodied in a chemical framework where its processing is modulated by preexisting constellations of amines, peptides, steroids, and other neurochemicals (Herbert, 1994). Moreover, fluctuations in this neuromodulatory framework are in large part driven by internal processes related to biological rhythms, moods, and motivational states that are not often addressed in psychological models. Similarly, in psychological theory, we attempt to define memory processes in relation to their functional characteristics, such as long term or short term, or to their phenomenal and behavioral manifestations, such as episodic, contextual, or procedural. In contrast, the neurophysiological perspective points to specific internal circuits that integrate cortical with limbic networks and that engage brain stem motivational and arousal regulatory systems. Although analysis of these memory circuits points the way to the adaptive, motivational control of each level of the neuraxis, it also raises the issue of how to relate neurophysiological mechanisms to psychological concepts of memory, motivation, and cognitive function.

In this chapter, we discuss the contribution of neurophysiological mechanisms and their associated internal states to motivation, personality, and psychopathology. We begin by

focusing on the neurophysiological evidence of separable motivational systems related to appetitive and defensive needs. A main emphasis is on the vertical integration of these systems, extending from the brain stem to the limbic systems to the cortex. We consider ways in which elementary motivational controls arising from brain stem and limbic regions shape more complex cortical processes of appraisal, concept formation, and self-regulation. As will be seen, individual differences in the appetitive and defensive systems are related to major personality dimensions such as extraversion/impulsivity and neuroticism/anxiety, respectively. In addition, we review models suggesting that individuals at the extreme of these dimensions, whose motivational systems tend to be under- or overreactive, will be most vulnerable to psychopathology. In simplest terms, excessive appetitive function can give rise to externalizing disorders, whereas extreme defensive function can underlie internalizing problems.

The chapter's second section attempts to fill in this preliminary framework by focusing on the regulatory functions carried out by the motivational systems. We suggest that *self-regulation* is a process through which motivational systems coordinate the functioning of component regulatory subsystems: The body is regulated through the endocrine, autonomic, and motor subsystems, and the brain is regulated through subsystems related to arousal and attention. An underlying theme is that the efficiency of the regulation will depend on the status of the regulatory subsystems; that is, if one of the subsystems is impaired or imbalanced, then the effective functioning of the motivational system as a whole may be compromised. Examining individual variability in these subsystems provides a broad view of children's sources of vulnerability and, at the same time, a more specific view of their actual symptoms. It also helps distinguish involuntary from voluntary forms of self-regulation and by so doing, helps underscore the difficulties inherent in children's attempts to cope with their problems.

The chapter's final section extends these regulatory functions to address self-organization. We propose that development does not proceed through a simple process of environmental "instruction," but through an internal process of selection guided by the child's developing motivational systems. By emphasizing these internal selective pressures, we explore the notion that children construct representations of the world that serve their motivational needs. In the chapter's final section, we return to an environmental perspective and consider ways that different environments may constrain the differentiation of the child's motivational systems. Depending on both the en-

vironment's input and the child's internal states, personalities can organize themselves along many different paths. Viewing development in terms of a self-organizing process provides a broader view of environmental influences and, again, a more specific view of the child's symptoms and experience.

MOTIVATIONAL SYSTEMS

Our discussion of motivational systems emphasizes two general systems, one related to appetitive needs and the other to defensive needs. We first lay out the anatomy and physiology of these systems, emphasizing their distributed nature across the nervous system. As will be seen, the brain stem pattern generation systems appear to provide complete packages of behavioral and autonomic response for simple creatures. For more complex organisms such as higher mammals, these systems become integrated with evaluative, mnemonic, and planning functions that have more extended, and less direct, influences on behavior. We then relate these systems to human personality, suggesting that individual differences in the reactivity of appetitive and defensive systems contribute to personality dimensions of positive emotionality (extraversion) and negative emotionality (neuroticism). Finally, we discuss the clinical vulnerabilities facing individuals falling at the extremes of these motivational system/personality disorders.

Defensive Systems

Instead of being localized within a small set of structures, the brain's defensive circuitry is widely distributed. This distribution reflects the brain's evolution: Defensive functions are patterned in discrete modules in the more primitive regions of the brain stem, are elaborated further with the evolution of the limbic regions, and are ultimately interwoven with memory and concept formation within the cortex. Whereas more primitive structures supported immediate responses to proximal dangers, the more recent circuits respond in a highly evaluative and planful manner to dangers that are extended in both space and time.

Beginning with the brain stem, the past 10 years has seen increased interest in a region known as the periaqueductal gray (PAG). The PAG receives sensory information from the immediate environment and organizes responses through descending projections to motor and autonomic cell groups within the medulla (see Figure 12.1). Of greatest interest is the PAG's organization in distinct columns

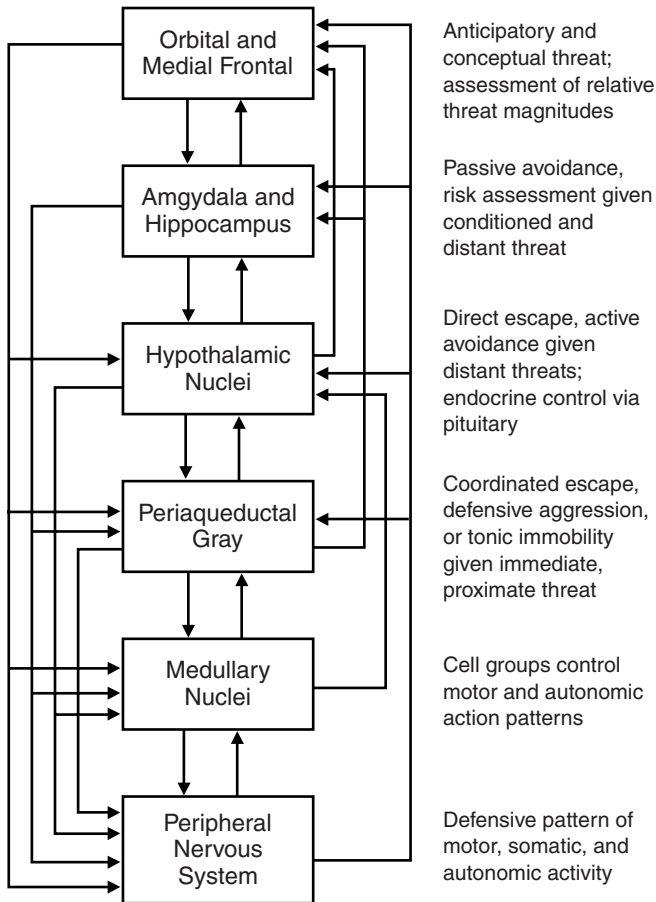

Figure 12.1 Schematic illustration of hierarchically organized defensive circuitry. Higher levels allow for more coordinated defensive reactions in response to threats that are more distant in temporal and spatial terms. Each level carries out increasingly sophisticated interoceptive as well as exteroceptive processing. Ascending and descending connections are extensive, allowing for a vertical integration within which diverse functional loops or activation patterns can emerge.

devoted to specific behavioral options. At least two of these PAG columns are devoted to defense. The caudal portion of the lateral column activates explosive escape behavior, as occurs when a prey animal is closely threatened by a predator but an escape route is available. In contrast, rostral regions of the lateral column elicit defensive aggression, as occurs when the threatened animal is cornered and cannot escape. Besides promoting active motor and autonomic responses, these defensive regions promote a nonopioid form of analgesia, serving to limit pain processing in defensive situations. In contrast to such active forms of coping, a ventrolateral column produces profound hyporesponsivity (i.e., tonic immobility), as occurs when an animal has been captured and copes by playing dead.

This passive action is accompanied by decreased sympathetic activation and an opioid analgesia. Thus, the PAG is capable of integrating three forms of defensive behavior (escape, defensive aggression, and tonic immobility), depending on the threat's proximity and the availability of escape routes (Bandler & Keay, 1996; Bandler & Shipley, 1994; Floyd, Price, Ferry, Keay, & Bandler, 2001).

The PAG defensive columns are reciprocally interconnected with major components of the limbic system. First, extensive connections exist between the PAG and various hypothalamic regions such as the anterior and ventromedial nuclei (Swanson, 2000). It has been suggested that the hypothalamus provides better sensory processing of more distant dangers, more time for organization of a suitable response, and thus what is referred to as *directed escape* (Gray & McNaughton, 1996). Second, the hypothalamus is reciprocally connected with the more recently evolved amygdala, which is in turn reciprocally connected with the PAG (Swanson, 2000). The amygdala allows conditioned fear reactions, where an originally neutral stimulus such as a sound predicts that a threat is present or imminent in the environment (LeDoux, 1996). In some cases, such reactions can be instantly triggered via direct inputs from the thalamus to the amygdala. The amygdala also receives extensive projections from sensory and association areas of the cortex, allowing it to modify fear responses based on complex combinations of highly processed information. Third, the hippocampus (which projects to both the amygdala and hypothalamus) may play a role in anxiety through a behavioral pattern called *risk assessment*. This occurs in conflict situations where both appetitive and defensive motives are active, as when an animal proceeds to forage in an area that was just vacated by a predator (Blanchard & Blanchard, 1988; Gray & McNaughton, 1996).

Each of these regions—the PAG, hypothalamus, amygdala, and hippocampus—are reciprocally connected with the cortex. In fact, distinct topographic circuits have been traced interconnecting the PAG, hypothalamus, amygdala, and frontal lobe (Floyd et al., 2001). Within the frontal lobe, two major emotion-related networks have recently been delineated (Carmichael & Price, 1995a, 1995b). The first is the *orbital network*, an interconnected set of roughly 13 regions located on the ventral surface of the frontal lobe. The orbital network is closely interconnected with adjacent ventral circuits within the temporal pole and insula. This complexity indicates multiple functions, but only a few have been characterized. For example, the orbital region involves a massive convergence of highly processed sensory and visceral information, suggesting that it is in-

volved in relating affective significance to cortical inputs or representations (Carmichael & Price, 1995b; Schoenbaum, Chiba, & Gallagher, 2003). In addition, the orbital region is involved in computing the relative magnitude of incentive input, as would be required in determining which is the greater of two threats (Schultz, Tremblay, & Hollerman, 2000). Finally, the orbital region appears to play a role in controlling behavior in conflict situations, when incentive values need to be reversed and reattached (Schoenbaum, Setlow, Nugent, Saddoris, & Gallagher, 2003). Thus, the orbital cortex seems well designed for recognizing complex and perhaps abstract threats, for determining their magnitude, and for adjusting representations when motivational conditions change.

In general, it appears that the orbital frontal cortex, associated ventral limbic networks (including the temporal pole and insula), and the amygdala are integral to elaboration of more primitive defensive reactions organized in the brain stem and hypothalamic centers. Several lines of evidence suggest that these ventral limbic networks are functionally exaggerated in humans with chronically activated defensive systems, such as those experiencing chronic anxiety (Tucker & Derryberry, 1992). It has also been suggested that interactions between the ventral limbic structures and the neostriatum (caudate and putamen) may promote highly routinized and habitual behavior. At an elementary level, engaging well-routinized action plans is critical to fight-or-flight behavior, and this modulatory influence may be adaptive at a cognitive level in humans, facilitating well-learned patterns of thought and action under stress. However, the pathological implications may be seen in behavioral compulsions and cognitive obsessions associated with exaggerated activations of the neostriatum and orbital frontal cortex in the chronic anxiety of Obsessive-Compulsive Disorder (Baxter, Phelps, Mazziotta, & Guze, 1987; Gehring, Himle, & Nisenson, 2000).

The second frontal network characterized by Carmichael and Price (1995a) is the *medial network*. Consisting of roughly 12 interconnected regions, the medial network subserves a number of functions. In general, it can be viewed as serving visceromotor functions complementing the orbital network's viscerosensory functions (Luu & Tucker, 2001). For example, specific areas within the medial network project to the same subcortical circuitry (e.g., amygdala, PAG) described earlier (Floyd et al., 2001). Presumably, the cortical input helps to fine-tune the unfolding fear response based on more elaborate input provided by the orbital network. Other medial regions, such as subfields within the anterior cingulate area, project to downstream cortical motor areas,

including the supplemental motor area and the motor cortex. The cingulate region has been described as providing the motivational drive that is articulated, in terms of axial, proximal, and distal components, in the subsequent motor areas (Goldberg, 1985). This may seem at odds with the fine-tuning function, though it is possible that the fine-tuning applies to involuntary defensive behaviors, whereas the drive function applies to more voluntary responses. Thus, the cingulate region may provide the conscious and active sense of *agency* involved in voluntary behavior.

It can be seen that defensive circuits are quite extensive and follow an evolutionary course. Whereas the more primitive regions provide adaptive mechanisms for dealing with simple, close, and immediate threats, the more recently evolved limbic and cortical networks allow for more complex evaluation of the danger based on multiple sources of information. Evaluation is able to extend into the future, enabling more flexible and planful behavioral responses. As will become clearer in subsequent sections, these more advanced functions remain regulated by subcortical mechanisms (and vice versa), such that all levels work together as the response unfolds. This form of *vertical integration* is characteristic of many functions within the brain and provides a useful perspective for viewing their development and pathology (Tucker, Derryberry, & Luu, 2000). We return to these issues after briefly describing the appetitive systems.

Appetitive Systems

The construct of an appetitive neural system has been explored by several researchers. The underlying circuitry has been discussed in terms of an "expectancy-foraging system" (Panksepp, 1998), a "behavioral activation system" (Gray, 1994), and a "behavioral facilitation system" (Depue & Collins, 1999). Panksepp's more primitive appetitive system regulates processes activated by states of need (e.g., hunger) and functions to activate approach/exploratory behavior along with an emotional state of desire. In contrast, the circuitry emphasized by Gray and Depue is more recently evolved and designed to detect conditioned signals of reward and nonpunishment. Given such signals, the circuitry facilitates approach behavior directed toward the positive incentive, along with emotional states of hope (given expected reward) and relief (given nonpunishment).

The actual neural circuitry underlying appetitive motivation has not been well characterized. It appears to be distributed vertically throughout the brain, flowing through some of the same structures involved in defensive functions.

For example, columns within the PAG appear to be related to appetitive functions of sex (Holstege & Boers, 2001) and drinking (Sewards & Sewards, 2000). At the limbic level, specific hypothalamic regions contribute to sex, hunger, and thirst. Animal research suggests that the basolateral amygdala plays a role in conditioned rewards (Schoenbaum, Setlow, et al., 2003), and human positron emission tomography (PET) scans have shown left amygdala activation during the viewing of positive pictures (Hamann, Ely, Hoffman, & Kilts, 2002). Finally, much evidence suggests that the orbital and medial prefrontal networks also contribute to appetitive motivation (e.g., Depue & Collins, 1999). Animal research suggests that reciprocal connections between the basal lateral amygdala and orbital cortex may encode information regarding expected rewarding outcomes (Schoenbaum, Chiba, et al., 2003). PET scans have shown orbital cortex and amygdala activity to covary as a function of stimulus category (food versus nonfood) in hungry humans (Morris & Dolan, 2001). Orbital neurons also encode the magnitude of a reward, firing more strongly to a monkey's preferred reward (Schultz et al., 2000).

One region that may play a unique role in appetitive behavior is the nucleus accumbens. The accumbens is a component in a reentrant loop through which cortical information is projected to the subcortical ventral striatum and eventually returned to the cortex by means of the mediodorsal thalamus and its projections to the frontal lobe. Activity within the loop passing through the nucleus accumbens can sustain activity in the medial prefrontal network. Multiple functions are involved, but a major one in relation to the accumbens loop is that of computing motivational intensity and regulating approach behavior (Depue & Collins, 1999). The loop as a whole, along with many other limbic and frontal regions, is modulated by dopamine projections from the brain stem's ventral tegmental region. Many theorists have focused on the core notion that reward-related dopamine firing facilitates approach behavior via the nucleus accumbens and its prefrontal projections (e.g., Depue & Collins, 1999; Pickering & Gray, 2001). This is an attractive model, but it should be noted that mediofrontal dopamine increases during stress (e.g., Benes, 1994), and thus a broader view of dopaminergic function seems necessary.

Another important question for understanding the influence of appetitive systems is how they engage not only hedonic responsiveness but the exploratory behavior that leads to new appetitive goals. In humans, positive affect, such as that induced by receiving a small, unexpected gift in a psychology experiment, leads to a more holistic, expansive cognitive set (Isen, 2000). In animals, there are sugges-

tions that behavior under rewarding conditions that are consistent with expectancies leads to engagement of a broad, contextual representation of the environment, supported by the dorsal limbic pathway (the hippocampus, posterior cingulate cortex, and anterior ventral thalamic nuclei; Gabriel, Kubota, Sparenborg, Straube, & Vogt, 1991). This context-updating mode of learning is suitable when ongoing events confirm the animal's contextual expectancies. It contrasts with the engagement of the ventral limbic, anterior cingulate, amygdalar, and mediodorsal thalamic circuit under conditions of context violation, when rapid adjustments of learning contingencies must be made. Whereas the context-updating, feed-forward mode of learning seems to dominate under appetitive conditions, the context-violation, feedback mode of learning seems to dominate under defensive conditions (Luu & Tucker, 2003).

Motivational Systems and Personality

One of the most interesting aspects of the appetitive and defensive motivational systems is their relevance to personality. Relating personality to the brain is a complex project facing difficulties from both psychological and physiological perspectives. From a physiological point of view, the motivational systems are so wide-ranging that individual differences may occur at different levels (e.g., brain stem, limbic, cortical components) within the system. A related issue arises from a psychological perspective, where it is difficult to ascertain what level of trait specificity (e.g., neuroticism, anxiety, social anxiety) is best suited for linking to a motivational system. Ultimately, we need to be as specific as possible, but at this point, the required knowledge is simply lacking. Therefore, we begin by addressing personality at a relatively general level and attempt to become more specific as the chapter proceeds. As will be seen, the more general traits map fairly well onto subcortical systems, whereas the more specific traits appear to require a cortical level of analysis.

The simplest approach links individual differences in appetitive and defensive systems to the general dimensions of extraversion or impulsivity and neuroticism or anxiety, respectively (H. J. Eysenck & Eysenck, 1985; Watson & Clark, 1992). Thus, a child with strong appetitive motivation should be sensitive to reward signals in the environment and should show vigorous approach behavior directed toward the rewards. Although some would speak of a dimension of "positive emotionality," this may be somewhat strong because children with strong appetitive motivation are not immune to negative emotions. Specifically, such

children may be vulnerable to frustration when their strong desires are blocked or delayed (Derryberry & Rothbart, 1997; Panksepp, 1998). Thus, terms such as “reward-oriented” and “impulsive” may be more appropriate. In any event, we would expect such children to be generally positive, with much of their positivity reflected in social affiliation, because others can be a strong source of reward. Behaviorally, they should tend to show vigorous approach behaviors, contributing to a generally high activity level. At a cognitive level, children with strong appetitive motivation should tend to focus on positive events and to be generally optimistic.

In contrast, children with a strong defensive system will be more sensitive to environmental punishment and will tend to avoid such events. Again, some theorists have used the dimension of “negative emotionality” to describe these children, but terms such as “anxious” and “fearful” seem more suitable. The reasoning here is that many anxious children will also experience much relief (or security or comfort) when their anxiety subsides. In general, anxious children will tend to show inhibited behavior (i.e., passive avoidance), though sometimes they may resort to active avoidance or even defensive aggression. Their cognition will tend to focus on impending or imagined dangers, along with a generally pessimistic view of the future.

One advantage of this type of dimensional approach is that it allows one to combine dimensions to appreciate more subtle personality differences. For example, a child’s strong appetitive system may be accompanied by either a weak or a strong defensive system. The impulsive child with a weak defensive system will be not only reward-oriented, but also somewhat fearless and poor at inhibiting approach in potentially punishing situations. In contrast, the impulsive child with a strong defensive system would be sensitive to both rewards and punishments in the environment and is likely to show inhibition, despite their strong approach, when punishment is present. Such a child may be quite emotional, showing hope, fear, frustration, and relief across different situations.

Extensions to Psychopathology

A related advantage of a dimensional approach is its relevance to psychopathology. An underlying assumption is that most cases of psychopathology are extreme expressions of normal personality: A motivational system becomes overreactive or underreactive, with this extreme reactivity placing the child at risk of developing maladaptive behavior. The causes of over- or underreactivity may be partly genetic or biologically based, but problems can also arise

from learning and the environment. Whatever the cause, specific neural structures become unbalanced, leading to various types of vulnerability.

For example, children with overreactive appetitive systems may show symptoms related to impulsive disorders (e.g., Attention-Deficit/Hyperactivity Disorder [ADHD], Conduct Disorder), such as oversensitivity to reward and approach behavior that is too strong or misguided. In contrast, children with underreactive appetitive systems may be prone to depressive symptoms, such as an insensitivity to reward, feelings of hopelessness, and difficulty mobilizing approach. On the defensive side, a child with overreactive defense systems will be most vulnerable to anxiety symptoms, such as excessive worrying about future events and inappropriate avoidance behavior. In contrast, those with a weak defensive system may be prone to disinhibited types of problems (e.g., undersocialized Conduct Disorder), resulting from their insensitivity to potential punishment and lack of inhibition (Derryberry & Rothbart, 1997; Fowles, 1994; Gray, 1994).

Further specification of symptoms can be made by considering the different levels within the motivational systems. Some children may show overactive defensive functions at multiple subcortical and cortical levels. This would be unfortunate, setting the child up for many forms of fear (e.g., Overanxious Disorder). For others, however, the reactivity may be focused at a single level within the system. Evidence suggests that panic attacks arise from overactivation within the PAG, in particular the columns related to explosive escape. Presumably, the circuits become disinhibited as serotonin levels drop, resulting in spontaneous attacks of extreme fear and an urge to escape (Graeff, 1991; Gray & McNaughton, 1996). Higher levels within the limbic system may play a stronger role in anticipatory forms of anxiety, such as those resulting from classical conditioning. Childhood phobias related to animals, other people, and school may have their roots in limbic structures such as the amygdala (Gray & McNaughton, 1996). Still higher levels within the cortex may underlie more subtle forms of anxiety, such as fears of failure, evaluation, and rejection, many of which are related to future uncertainties. Thus, different anxious symptoms can be predicted based on the different levels within the defensive circuitry. Nevertheless, given the integration seen across the levels of the defensive system, one would expect anxious symptoms to be related, co-occurring in different children to different degrees. For example, a child with panic problems (brain stem) may develop anticipatory anxiety (limbic) and even evaluation anxiety (cortical) regarding his or her panic attacks.

A multidimensional approach is also helpful in predicting the interactions that may increase vulnerability. For example, the children most likely to show impulsive problems should be those with a strong appetitive system accompanied by a weak defensive system. Such children will tend to vigorously approach a potential reward, without fear or inhibition given potential punishments. However, if the strong approach tendency is accompanied by moderate or strong fear, then the child will have some degree of inhibition over his or her impulsivity. Conversely, the children most vulnerable to anxiety disorders should be those with a strong defensive system and a weak appetitive system. The lack of reward sensitivity and approach tendencies makes it easier for the child to avoid certain threatening situations, especially social situations. If the anxiety is accompanied by moderate or strong appetitive tendencies, then the potential rewards from social interaction might mobilize approach and thus overcome the avoidant tendencies. Although more research is needed, recent studies provide preliminary support for such predictions (Caspi, Henry, McGee, Moffitt, & Silva, 1995; Eisenberg et al., 2001; Quay, 1993).

As can be seen from these examples, these simple dual-system approaches also provide a useful perspective for understanding comorbid disorders. For example, a good proportion of children suffering from ADHD also experience anxiety (Pliszka, 1992). This would make sense if such children possessed a strong appetitive system that promoted the hyperactive approach tendencies of ADHD, along with a strong defensive system that promoted the anxiety. Another example is comorbid anxiety and depression, which appears to be quite common in anxious adults (Mineka, Pury, & Luten, 1995). Here, one would suspect a strong defensive system along with a weak appetitive system, with the weak appetitive system contributing to the anhedonia and low approach symptoms of depression.

Interestingly, most anxious depressions begin with an anxious rather than depressed episode. One explanation is that prolonged defensive reactivity to stress may progressively suppress appetitive functioning, eventually leading to a depressive state. The reduced appetitive functioning could be due to inhibitory projections from the defensive to the appetitive system, or from the depletion of a crucial neuromodulator (e.g., dopamine) used by both systems. In other instances, a sudden drop in appetitive functioning may be brought on by environmental changes, such as the loss of a parent or good friend. The drop in appetitive functioning may disinhibit activity in the defensive system (by weakening the inhibitory connections), again resulting

in depression accompanied by anxiety. It can be seen that this type of dual-system model provides multiple approaches to understanding comorbid disorders.

To summarize, we have traced the vertical structure of two complementary and interacting motivational systems. This general framework provides a useful approach to conceptualizing personality differences, suggesting that personality is grounded in relative strengths of appetitive and defensive systems. Moreover, it provides a useful starting point for considering childhood psychopathology, which can be tied to imbalances in a child's tendencies to approach rewards and/or avoid punishments. Although it is beyond the scope of this chapter, we note that future research will describe additional motivational systems, such as one related to nurturant forms of behavior (Depue & Morrone-Strupinsky, in press; MacDonald, 1992). Individual differences would most likely be related to a personality dimension of agreeableness/hostility, which would advance our understanding of the more callous and aggressive forms of psychopathology.

Hierarchical Organization

Given such extensions to personality and psychopathology, it is worth briefly returning to the construct of hierarchical organization illustrated in Figure 12.1. Theorists have long emphasized the hierarchical structure of the brain, a structure evident from phylogenetic, ontogenetic, and functional perspectives. The classic approach has been a top-down approach, viewing development as a process through which higher regions exert increasing control over more primitive regions. For example, primitive panic-like forms of fear may be inherent in the brain stem, but these are gradually brought under control by the anticipatory, evaluative, and memorial capacities of the limbic and cortical regions. With development, representations provide increasing control over emotions such as hope, fear, and anger, shaping them in terms of cultural beliefs, values, and rules.

This form of top-down model often views psychopathology as resulting from failures at the highest levels, such that the motivations or behaviors are inappropriately released from inhibition. A child may become chronically anxious, for example, because cortical representations or inhibitory mechanisms are not strong or accurate enough to construct the situation as safe and inhibit the fear. Or, from a more recent cognitive perspective, some representations may be too strong or biased (e.g., catastrophic thinking) and function to amplify more primitive fear tendencies. Rather than simply disinhibiting subcortical fears, the cor-

tex can also directly enhance the fear to problematic levels. Much current theorizing speaks in terms of disinhibition or dysregulation, and clearly there is a lot to be gained from this perspective.

In contrast to such top-down approaches, however, other theorists have emphasized bottom-up approaches, in which lower-level processes influence higher levels. Physiological bases can be seen in the ascending projections illustrated in the defensive circuitry of Figure 12.1, which appear to be as extensive as the descending connections. Given that subcortical regions tend to precede cortical regions in development, a child born with strong subcortical fear circuitry may subsequently learn to view and think about the world in an anxious way. Thus, subcortical regions provide a motivational foundation on which cortical representations are framed. As described earlier, this type of approach suggests that some forms of psychopathology develop because overreactive or underreactive motivational systems shape cognition in a maladaptive way. In subsequent sections, we describe ascending regulatory functions, such as the dopaminergic regulation of frontal lobe functions. Imbalances in the subcortical dopamine projections appear influential in disorders such as ADHD and Schizophrenia (Benes, 1994). At even lower levels, peripheral cortisol has been found to regulate activity in the brain stem, limbic, and cortical regions, providing a hormonal pathway through which vulnerabilities may arise (Gunnar, 1994). Although this bottom-up approach has not been as influential as the top-down approach, it is likely to gain in power as we learn more about the biological nature of the nervous system, in particular, its relations to the endocrine and immune systems.

Most recently, many theorists have come to view the bottom-up and top-down frameworks as complementary. This can be done in different ways, but a useful example can be seen in the notion of vertical integration. As alluded to earlier, the idea is that the nervous system can be viewed as a set of vertically evolved modules interconnected through overlapping reciprocal connections, as depicted in Figure 12.1. Activation may arise at several levels within this system, depending on the nature of the input and the current reactivity of the individual modules. But regardless of whether it begins relatively high or low in the system, activation will spread such that all components are brought into play. When a child becomes anxious, we see changes in peripheral cortisol and autonomic activity, as well as coordinated activity within the medulla, PAG, hypothalamus, amygdala, and cortex. In some cases, the primary flow may be top-down; in others, it is bottom-up. In either case, the

two flows will work to support one another, with the bottom-up flow establishing the general framework and the top-down serving to fill in the details of the motivational state. To some extent, this vertical processing can be viewed as a microgenetic process, characterized by movement from general to more specific functions (Derryberry & Tucker, 1991).

Because information and regulatory activity run in both directions, the stage is set for dynamic interactions between the various hierarchical levels. For example, fear-related excitation ascending from the amygdala might trigger inhibition from the cortex, such that a negative feedback loop is established and anxiety is suppressed. In other instances, ascending excitation may trigger descending excitation, setting up a positive feedback loop that amplifies cortical beliefs of danger and subcortical feelings of fear. Such patterns of self-amplifying activity are common in both defensive and appetitive situations and constitute serious challenges to self-regulation. We introduce additional examples of dynamic interactions in later sections of the chapter.

Although approaches emphasizing simple motivational systems are helpful, it is clear that they face several shortcomings. On the one hand, these approaches focus on motivational systems in isolation, without relating them to other brain systems that may also contribute to psychopathology. In addition, the models are fairly good at predicting reactive responses and general symptoms, but they do not shed much light on the child's active efforts to cope with these symptoms. Furthermore, such models remain rather vague regarding the specific nature of the child's symptoms. The next section begins to address these issues by focusing on the regulatory functions carried out by the motivational systems.

MOTIVATIONAL SYSTEMS AND SELF-REGULATION

Recent years have seen an increasing interest in processes referred to as emotion regulation, behavior regulation, and self-regulation. Unfortunately, these terms are often used vaguely and interchangeably, making it difficult for researchers to communicate effectively. Our approach attempts to define the regulatory processes as clearly as possible. In this view, a regulatory process is one that does not directly transmit or process information, but rather adjusts (e.g., by facilitating or inhibiting) the processing in the systems that it targets (Wise, 1987). Thus, the motivational

systems described earlier are actually high-level regulatory systems; they respond to various types of rewards and punishments by adjusting the reactivity of other subsystems within the brain. These subsystems are themselves regulatory in nature, adjusting the processing in other information-processing systems. To an extent, the motivational systems can be viewed as forming the highest level in a hierarchy of regulatory systems. Thus, Panksepp (1998) suggests that the motivational systems function as “executive” regulatory systems within the brain.

Regulatory Subsystems

In the following paragraphs, we discuss six general types of regulation orchestrated by the motivational systems. As illustrated in Figure 12.2, the appetitive and defensive systems regulate three types of peripheral systems, the motor,

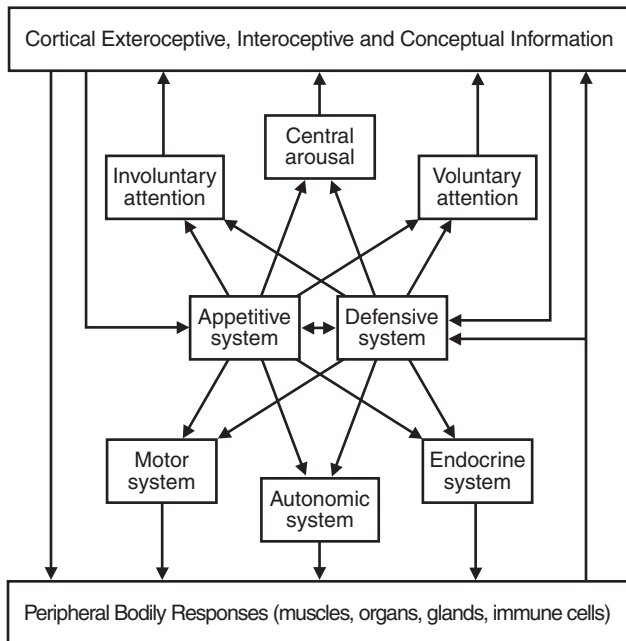

Figure 12.2 Simplified illustration of the major regulatory subsystems controlled by appetitive and defensive motivational systems. Cortical and subcortical input is monitored by motivational systems. Given a significant input, the motivational system coordinates responses via motor, autonomic, and endocrine adjustments and also coordinates perceptual and conceptual processing via adjustments of central arousal systems (dopamine, serotonin, norepinephrine, acetylcholine), involuntary attentional systems, and voluntary frontal attentional mechanisms. Lateral ascending lines represent interoceptive information from the body. Lateral descending lines represent cortical and direct thalamic information to the motivational systems. Not illustrated are direct and cortical inputs to the motor system, as well as reciprocal inputs from the six regulatory systems to the motivational systems.

autonomic, and endocrine systems, to produce complex behavior. To support this behavior, the motivational systems also recruit central regulatory systems involved in modulating perceptual and conceptual activity in the forebrain. These central systems are involved in processes of arousal, involuntary attention, and voluntary attention. By adjusting these regulatory subsystems, ongoing motives can orchestrate a state of reactivity throughout the organism that is adaptive, given ongoing needs. Thus, motivational systems function at a high level to coordinate activity in the body and brain.

A major thrust of our approach is based on evidence that individual differences arise not only in the motivational circuitry itself, but also in the regulated subsystems. Although the systems are designed to be adaptive, individual variability will cause the overall motivational state to differ in efficiency across individuals. In most cases, the states are generally efficient and adaptive, but for some, imbalances in arousal or attention may lead to states that are maladaptive; that is, the regulation is ineffective such that appetitive motivation often leads to frustration rather than reward, and/or defensive states result in fear rather than relief. We hope to show that considering the regulatory challenges within the subsystems provides a more specific view of the source and nature of the child’s symptoms.

Regulation of Peripheral Arousal

Traditional approaches to motivation and emotion have long emphasized the role of the body. Consistent with these approaches, all levels within the motivational systems (i.e., PAG, hypothalamus, amygdala, cortex) project extensively to cell groups in the medulla and hypothalamus related to autonomic and endocrine activity, respectively (Holstege, Bandler, & Saper, 1996). Although older models emphasized a unitary notion of “peripheral arousal,” motivational states are now known to involve specific patterns of activity across the autonomic and endocrine systems. These patterns are important in at least two ways. They provide a peripheral physiological state, involving multiple organs and glands that supports the motor response required in an appetitive or defensive situation. In addition, the peripheral adjustments feed back on the brain as interoceptive sensory information, whose processing gives rise to the emotional feelings (e.g., fear, hope, relief, frustration) that accompany the motivational state. In later sections, we argue that such emotional feelings are represented in the cortex and play a central role in guiding motivated behavior.

Individual differences in the autonomic and endocrine levels systems can have profound effects on the efficiency

of the motivational state. At the endocrine level, for example, the relatively long-lasting secretion of cortisol promotes energy utilization throughout the body, an adaptive function for appetitive and especially defensive goals. However, cortisol also crosses the blood-brain barrier, where it potentiates fear-related circuitry in the amygdala (Schulkin, McEwen, & Gold, 1994). Thus, a child with an intense or prolonged cortisol response can set up a positive feedback loop that intensifies and prolongs his or her anxiety. Research by Gunnar and her colleagues (Stansbury & Gunnar, 1994) has found interesting differences in cortisol patterns between children. When faced with a new social situation, children who are more outgoing show an initially strong but rapidly recovering cortisol response as they engage other children. In contrast, more inhibited children show an initially weak cortisol response but then more intense and prolonged response when they finally approach the other children (Gunnar, 1994).

The autonomic nervous system is another important source of variability. One area of active interest has been the balance between sympathetic and parasympathetic divisions, as assessed through constructs such as vagal tone (Porges, Doussard-Roosevelt, & Maiti, 1994). In general, parasympathetic dominance, as reflected in a higher vagal tone, appears related to several positive emotional and behavioral outcomes (Beauchaine, 2001). Children with weak vagal tone may show delays in responding in motivational situations, as well as prolonged responses and a slower return to homeostasis. This peripheral imbalance may enhance negative affect and impair more central regulatory processes involving attention. It is worth noting that the peripheral autonomic nervous system is not entirely separate from the brain's central arousal systems. Links have been drawn between the peripheral sympathetic system and the central noradrenergic arousal system (see later discussion). Thus, peripheral imbalances between sympathetic and parasympathetic divisions may also be reflected in the central monoamine imbalances related to problems of depression and anxiety.

Motor Regulation

Traditional motivation models focused on motor responses as the basic target of motivational regulation. Again, this would be a primarily regulatory function; rather than directly transmitting information or activating a response, the motivational circuits potentiate a set of responses that might be adaptive given the current situation. The simplest example here would be functioning at the level of the PAG, where a defensive state potentiates three response options: escape, defensive aggression, and immobility. Converging

environmental signals, conveying the threat proximity and escape routes, can then release the most appropriate reaction. Response processing will be more complex at higher levels such as the cortex, but again, the motivational influence is primarily regulatory, potentiating one set of options and perhaps depotentiating others.

At higher levels of the motor system, an important framework has come from the recognition of dual-motor pathways within the frontal lobe (Goldberg, 1985; Passingham, 1987; Tanji & Shima, 1996). In the mediodorsal pathway (cingulate gyrus and supplementary motor area), actions appear to be organized through feed-forward control, launched toward goals set by internal urges. In the ventrolateral pathway (orbital and lateral frontal), actions appear to be organized through feedback control, in which external sensory targets are used as criteria for adjusting the action sequentially. Although these are action regulation systems, they appear to be based on motivational controls from the limbic networks at the dorsal (medial) and ventral (orbital) bases of the frontal pathways (Luu & Tucker, 2003; Tucker, 2001).

Various psychopathologies may be facilitated by imbalances between these two action regulation systems. Neurological evidence indicates that with extensive lesions of the cingulate cortex and mediodorsal pathway, subjects show akinetic mutism or pseudodepression, as if losing the projectional, visceral, internal feed-forward control over behavior generally (Blumer & Benson, 1975; Goldberg, 1985). With lesions of the orbital frontal lobe, patients show a pseudopsychopathic mode of behavior, as if losing the inhibitory feedback control over behavior provided by the viscerosensory function (Blumer & Benson, 1975; Luu & Tucker, 2003). Although we have little evidence of overreactivity in these motor systems, it is reasonable to predict that an imbalance favoring the medial or projectional system would potentiate impulsive appetitive tendencies and interfere with the constraint required in defensive states. In contrast, a strong ventrolateral pathway may allow individuals to function more effectively in defensive states, but their feedback control and checking may impair appetitive approach behavior.

Regulation of Central Arousal

Another important regulatory mechanism involves connections from the motivational systems to the reticular cell groups in the brain stem. Most relevant here are the norepinephrine projections from the locus coeruleus, the serotonergic projections from the raphe nuclei, the dopaminergic projections from the ventral tegmental area, and the cholinergic projections from the nucleus basalis. Each of these

systems sends extensive ascending projections to the fore-brain, making them capable of modulating perceptual, conceptual, and response processing in the cortical and limbic regions. A motivational state arising in the amygdala may adjust firing rates in all four of these arousal systems. Because each system has distinct (though overlapping) cortical targets and distinct modulatory effects, the amygdala can thus establish a state of general cortical readiness that is appropriate to the motivational state. Although these complex modulatory states remain beyond current understanding, we can begin to see how certain components may contribute to adaptive processing. For example, some defensive states may feature strong dopaminergic activation, which tends to focus attention on the source of threat and to bias processing in favor of relatively routinized responses. In contrast, appetitive states may recruit noradrenergic projections, which serve to enhance signal: noise ratios, enable attentional shifts, and broaden the scope of processing (Derryberry & Tucker, 1991; Tucker & Derryberry, 1992; Tucker et al., 2000).

Individual differences in the central arousal system appear crucial to psychopathology. Although they contribute to many motivational states, the arousal systems tend to be strongly recruited in stressful or defensive contexts. If the stress is prolonged, the neurochemical systems can become depleted or at least imbalanced. Such imbalances in norepinephrine, serotonin, and dopamine form the foundation of biological models of depression and are the primary targets of pharmacological treatments (Davis, Charney, Coyle, & Nemeroff, 2002). For example, depletions in projections related to appetitive approach behaviors (e.g., dopamine, norepinephrine) may contribute to the anhedonia and impaired approach evident in depression. These systems have also been implicated in anxiety and impulsive disorders. For example, serotonin appears to exert a general inhibition of brain stem (PAG) and limbic circuits related to fear and aggression (Depue & Spoont, 1986; Graeff, 1991). If serotonin is too low, then normally constrained response patterns can be disinhibited, resulting in panic attacks and perhaps anger attacks (Barlow, Chorpita, & Turovsky, 1996). Furthermore, the ascending arousal systems contribute to a wide range of cognitive processes. Dopaminergic projections to the frontal lobe enable working memory, attention, and other frontal functions. Recent research suggests that an optimal level of dopaminergic facilitation is required for effective frontal control; if dopamine is too high or too low, executive functions can suffer (Arnstein, 1998). Thus, a child with low dopamine may have trouble focusing attention and show symptoms related to ADHD. In contrast, a child with high dopamine, as can occur in anxi-

ety, may become overfocused and have difficulty shifting attention. Serotonin, norepinephrine, and acetylcholine also play important roles in regulating attentional processes.

Although the central arousal systems appear crucial to a variety of disorders, it is clear that their effects are complex and that more research is needed. Each of these neuromodulators functions through multiple receptors, exerting distinct effects depending on the targeted receptor (Up-house, 1998). In addition, activity in the cell bodies is not simply regulated by motivational systems, but is also subject to a variety of rhythmic, peptide, and hormonal (e.g., cortisol) effects (Herbert, 1994). Nevertheless, studying these systems is an area of intense activity, and progress will accelerate in the coming years.

Regulation of Attention

Limbic and brain stem motivational circuits also project on more specific regulatory systems involved in attention. The attentional systems are closely related to the arousal systems, but appear to exert more specific and flexible effects on their targets. In general, attention refers to a selective facilitation of specific information that arises apart from the automatic activation of input pathways. In other words, incoming information may be to some extent processed “automatically” without attention. When attention is aligned with an activated pathway (or in advance of its activation), that information is facilitated for extended processing. Posner (Posner & Raichle, 1994; Posner & Rothbart, 1998) has described a “posterior attentional system” responsible for the involuntary orienting of attention from one spatial location to another. The system consists of a network with separable regions contributing to attentional “disengagement” (parietal cortex), “movement” (superior colliculus), and “engagement” (thalamic pulvinar nucleus). This posterior network is labeled “involuntary attention” in Figure 12.2.

Whereas the orienting system is thought to function in a primarily reactive manner, another system, the anterior attentional system, is thought to be responsible for voluntary control (see Figure 12.2). The anterior system involves distributed circuits within the frontal lobe, with the anterior cingulate region playing a pivotal role. The anterior system regulates the posterior system so as to provide voluntary control over orienting. It also functions to inhibit dominant response tendencies, to inhibit dominant conceptual associations, and to monitor and correct erroneous responses (Posner & DiGirolamo, 1998; Posner & Raichle, 1994). A similar set of executive functions can be found in Shallice’s (Shallice et al., 2002; Stuss, Shallice, Alexander, & Picton, 1995) construct of a “supervisory attentional system.”

In describing these processes, we place most emphasis on the voluntary attentional mechanisms and the role they play in facilitating motivated behavior. We first describe the targets of the attentional regulations, which include exteroceptive, interoceptive, and conceptual information. We then consider individual differences in such attentional control, illustrating ways poor control may impair motivational function and thereby promote psychopathology.

Exteroceptive Input

Adaptive functioning often requires flexible attention to multiple sources of external information. In appetitive contexts, a child who can be attentive to both the rewarding goal and potentially frustrating obstacles is best able to avoid the obstacles and obtain the reward. In a defensive situation, the child who attends to both the threat and the sources of safety can best avoid the threat, approach the source of safety, and obtain relief from anxiety. In more complex situations, such as social situations, the child may need to attend to several other children simultaneously, monitoring positive and negative signals through several channels (e.g., facial expressions, tone of voice). If attention is biased or limited, then the flexibility required in such situations can easily be compromised (Derryberry & Reed, 1994b; Derryberry & Reed, 2002).

Much evidence has demonstrated attentional biases related to personality and clinical problems, though this is primarily true for defensive rather than appetitive functions. Anxious adults allocate greater attention to threatening visual information, such as a negative word or photograph or a failure-related signal in a game context (for review, see M. W. Eysenck, 1997). Similar biases have been found in children (Vasey & Daleiden, 1996). Our research with college students suggests that the underlying problem is not one of moving attention toward environmental dangers; rather, the difficulty lies in disengaging and shifting from such threats once they are engaged (Derryberry & Reed, 1994a). In addition, anxiety promotes focusing or narrowing of attention. Such narrowing may take the form of focusing on a central portion of the visual field at the expense of the peripheral field (e.g., A. Mathews & Macintosh, in press) or focusing on local details of a figure at the expense of the global form (Derryberry & Reed, 1998). These cognitive effects are reminiscent of the routinized and restricted attention engaged by strong ventral limbic and orbital frontal control in defensive responses.

Many of these biases probably arise from motivational effects on involuntary attentional mechanisms. As discussed in more detail later, some children may be able to attenuate these effects by voluntarily controlling atten-

tion. If attention becomes overfocused, the child may be able to broaden attention and regain perspective. If attention becomes too strongly engaged, he or she can intentionally disengage and attend to something else (Derryberry & Reed, 2002).

Interoceptive Input

A more subtle form of perceptual regulation involves attention to interoceptive feelings. Although feelings tend to be neglected in much of the literature, their regulation is evident even at the primitive level of the PAG. In defensive states, the PAG can recruit both opioid and nonopioid analgesic mechanisms to suppress pain information that might prove distracting and interfere with efficient coping (Bandler & Keay, 1996). Given the more complex interoceptive representations afforded by the cortex, more sophisticated attentional regulation can be implemented.

Self-report data suggest that the cortex can represent at least three types of feelings: positive affect, negative affect, and energy (e.g., Matthews, 1997). These can be combined with other somatic information in more complex representations of emotions, such as fear, relief, pleasure, and frustration. When related to other information, interoceptive feelings can be extremely useful in evaluating incoming information (stimulus-outcome evaluations) and potential responses (response-outcome evaluations). Such evaluations are consistent with findings regarding the orbital and medial prefrontal networks (e.g., Schoenbaum, Chiba, et al., 2003).

Nauta (1971) first suggested that disconnections in the frontal lobe may promote an "interoceptive agnosia," where a person can recognize an object but fail to perceive its affective significance. In normal behavior, Nauta pointed out that linked affective information can serve as "navigational markers" or "affective reference points" for guiding behavior. More recently, Damasio (1994) has used similar ideas in his model of "somatic markers": internal affective information that allows a rapid affective guidance of behavior. Again, a basic assumption is that deficits or imbalances in these markers may lead to poorly directed and organized behavior, and to psychopathic behavior in extreme cases.

In regulatory terms, individuals may vary in their ability to use attention to modulate aspects of their interoceptive state. For example, some children may be able to suppress their fear by shifting attention from anxious feelings. Similarly, some may be able to suppress their appetitive behavior by disengaging from hopeful rewarding sensations. Other forms of interoceptive regulation may focus more specifically on energetic feelings. Children

may learn to initiate difficult activities or to sustain effortful behavior by amplifying the energetic feelings arising from the body. Although such processes are difficult to study, we suspect that they provide a rather basic form of self-regulation. Such control most likely depends on voluntary attentional mechanisms of the frontal lobe (Derryberry & Rothbart, 1997).

Conceptual Processing

Perhaps the most important form of regulation arising from motivated attention is that involving conceptual processing. Such regulation is a function of Posner's anterior attentional system and Shallice's supervisory attentional system. One aspect of this regulation concerns the inhibition of dominant or prepotent conceptual associations, allowing concepts to be rearranged to form new ideas and beliefs. For example, an anxious child faced with a threatening event, such as an upcoming test, may use attention to manipulate information relevant to his or her potential performance. The child may attend to the test's content and difficulty, as well as to his or her own intelligence and ability to study for the exam. If done objectively with little bias, such conceptual regulation should allow the child to come up with a rational and effective coping strategy or plan of study.

The problem for many anxious children is that the appraisal processes can become negatively biased and relatively automatic (Beck & Clark, 1997). Anxious children are likely to overestimate the degree of threat and to underestimate their coping ability, thereby increasing their anxiety. However, if attention can be used to inhibit these automatic associations, the child should be able to more accurately appraise the threat (e.g., "The test will be hard, but it's not that important and it's not immediate") and his or her ability to cope ("I'm not good at tests, but I can study harder") at the conceptual level. Such conceptual regulation will not be easy for the child (or even for adults), but it provides a direct way through which the defensive system can help attenuate fear.

Other examples can be found in the conceptual processing underlying causal attributions. Evidence suggests that anxious people tend to attribute negative events to internal causes, often blaming themselves for negative outcomes (Mineka et al., 1995). Although internal attributions are not necessarily inaccurate or maladaptive, they do tend to enhance anxious and depressive symptoms. If this automatic tendency can be inhibited, however, then a less debilitating attribution can be constructed (e.g., "I failed the test because math is difficult and not because I'm dumb"). Similarly, depressed and anxious individuals tend to make

uncontrollable attributions, feeling that there is nothing they can do to improve the situation. If this belief can be suppressed, they may be able to view a negative outcome as controllable and then formulate new options for coping in the future (e.g., "I failed the test, but I can study harder in the future").

Individual Differences in Attentional Control

It should be evident from the previous examples that attention can play a role in regulating the appraisal and attributional processes thought to be so important to emotion. Unfortunately, many of these regulations are quite difficult, because the regulated processes involve automatic activation or involuntary attentional biases. Thus, individual differences in the voluntary attentional ability to constrain more reactive processing can have crucial effects on the efficiency with which motivational states function.

Individual differences in voluntary attention have been of special interest in the developmental literature. Rothbart and her colleagues (Rothbart, Ahadi, & Hershey, 1994; Rothbart, Derryberry, & Posner, 1994) have investigated a dimension of "effortful control" thought to reflect individual variability in the anterior attentional system. Effortful control is assumed to function by allowing the child to suppress more reactive tendencies associated with appetitive and defensive processes. Consistent with this notion, effortful control and similar measures have been found related to a variety of positive outcomes. Children with good control tend to show more positive affect, less negative affect, more empathy, more social competence, enhanced conscience, and enhanced compliance (e.g., Eisenberg, Fabes, Guthrie, & Reiser, 2000; Kochanska, Murray, & Harlan, 2000; Rothbart, Ahadi, et al., 1994). Research also suggests that effortful control may serve as a protective factor, limiting the vulnerability arising from extreme appetitive or defensive reactivity. Eisenberg and her colleagues (2001) found internalizing behaviors in 4- to 8-year-olds to be predicted by low effortful control, low impulsivity, and sadness, whereas externalizing problems were related to low effortful control, anger, and impulsivity. However, another study found effortful control to predict internalizing and externalizing problems in a nonlinear way, with low and high levels of control associated with problem behaviors (Murray & Kochanska, 2002).

One of the difficulties inherent in research on effortful control is that the individual difference measures often blend together a variety of attentional and response-related processes. The capacity is most likely multidimensional, making specific predictions difficult. It is also likely to

rely on several different frontal regions. In a recent fMRI study, participants were asked to view negative photos and cognitively reappraise them. This effortful reappraisal tended to decrease negative affect, but to differing degrees in different individuals. Across individuals, success in reducing negative affect was positively correlated with anterior cingulate activity, the general region of Posner's anterior attentional system. However, the reappraisal process itself was most strongly accompanied by activation of the lateral and medial prefrontal regions, along with decreased activation in orbital and amygdaloid regions (Ochsner, Bunge, Gross, & Gabrieli, 2002).

Our research with college students has tried to simplify this situation by measuring voluntary regulation that is primarily attentional. We use a 20-item self-report measure of attentional control along with reaction time tasks designed to target specific attentional processes. We have found the Attentional Control scale to predict attentional performance in perceptual, conceptual, and response-related tasks (Derryberry, 2002). One study employed a design where an initial cue drew attention to either a threatening location (i.e., where points were likely to be lost) or a safe location (i.e., where points were unlikely to be lost). All anxious participants showed delays in disengaging attention for a cued threatening location for 250 milliseconds. By 500 milliseconds after the cue, however, anxious persons with good attention were able to disengage and shift to the safer location, whereas those with poor attention still had difficulty shifting from the threatening location. This pattern suggests that anxious people with poor voluntary attention will be more vulnerable when it comes to coping with threat, because they have difficulty shifting from danger to find a source of safety (Derryberry & Reed, 2002).

More recently, we have begun collecting data relating attentional control to various forms of coping. Students with good attention tended to employ more difficult but effective strategies, such as active coping, planning, and positive reappraisal. In contrast, those with poor attention favored simpler and less effective strategies, such as denial, disengagement, and venting. Some coping strategies were predicted by motivational as well as attentional tendencies. For example, the positive reappraisal strategy was associated with good attention and a strong appetitive tendency, restraint coping was predicted by good attention and strong defensive tendencies, and venting was predicted by strong defensive tendencies and poor attention (Derryberry & Pilkenton-Taylor, 2005).

In general, we suspect that attentional skills enable children to incorporate more complex and more effective coping strategies into their defensive and appetitive moti-

vation. In terms of Figure 12.2, the functional capacity of the voluntary attentional link may prove pivotal to effective coping. Children with good attention should be better able to inhibit reflexive biases, to assess more information, and thereby to arrive at a more adaptive coping strategy. Unfortunately, children with poor attentional control may have to rely on simpler and less effective techniques such as distraction and venting. Such techniques may often fail, leaving the child with increasing anxiety or frustration and a desire to avoid the situation. If the situation is avoided, then the child loses the opportunity to learn about the threats and new ways of coping.

To summarize, we have argued that motivational systems exert wide-ranging regulatory effects. Regulation of motor, autonomic, and endocrine systems prepares the peripheral body, and regulation of central arousal and attention guides the processing of exteroceptive, interoceptive, and conceptual information. If certain regulatory subsystems are impaired, then the motivational process as a whole will suffer, leaving the child vulnerable to impulsive and anxious disorders. To understand these disorders, it is necessary to focus on the regulatory subsystems and to determine how their functioning may enhance or impair overall motivational performance. We suspect that the capacity for voluntary attentional control may prove to be the most influential of these regulatory effects.

Interactions between Motivational Systems

Our discussion so far has been simplistic in implying that only one motivational system is active at a time. In reality, most environments contain both positive and negative signals, resulting in the simultaneous activation of appetitive and defensive systems. Similarly, at a conceptual level, most of the child's thinking will consist of both positive and negative elements, as is usually the case in thinking about the self or the future. By considering contexts in which motivational systems might interact, a more informed view of self-regulation can be attained.

Reactive Interactions

The most common type of interaction involves the inhibition of appetitive motivation by defensive motivation. Positive and negative incentives are present in the environment, but the defensive system inhibits approach behavior to protect the individual. We have suggested that this type of behavioral inhibition provides the child with an initial, reactive means of self-control (Derryberry & Rothbart, 1997). The effectiveness of this regulation depends on both the strength of the approach motive and the strength of the

defensive inhibition. As mentioned earlier, the regulation of approach will become increasingly effective as appetitive motivation decreases and defensive motivation increases. Thus, children with strong appetitive and weak defensive systems should be most vulnerable to impulsive, disinhibited forms of behavior.

To provide a less familiar example, anxious children often find themselves in conflict situations, where they might want to join other children in play but their fear holds them back. In some instances, the fearful child's attention may be caught by some positive signal, such as the smiles or laughter of the other children. If attention orients to these signals, their impact on the child's appetitive system is enhanced, leading to a progressive increase in the desire or tendency to approach. At some point, the appetitive motivation may surpass that of the defensive system, such that the child approaches and plays with the other children. As illustrated, this can be an entirely reactive form of regulation, driven primarily by changes in the environmental balance of positive to negative signals.

In brief, we have described two simple forms of reactive regulation arising from interactions between motivational systems. The defensive system can constrain approach behavior, and the appetitive system can attenuate fearful behavior. Viewing this regulation as a temporal process, in which a less dominant system progressively weakens the stronger system, provides a useful framework for more voluntary forms of self-control.

Voluntary Self-Control

In this view, self-control or "will" arises in a situation where two motives are in conflict, with the initially weaker motive recruiting voluntary processes to supersede the dominant motive. More specifically, the weaker motive can employ attention to suppress the exteroceptive, interoceptive, and conceptual pathways that fuel the stronger motive and to facilitate the pathways that support itself. These attentional influences are difficult and energy-demanding, resulting in feelings of effort and agency on the part of the person. These internal feelings of resistance, effort, and agency are central components of the general experience of will.

For children with strong appetitive motivation, one of their common challenges will be to bring their impulsivity under control. They may often find themselves in situations where the appetitive system is dominant and the defensive inhibitory system is active but not strong enough to rein in the approach tendencies. However, if the defensive system can access voluntary frontal capacities, it can amplify its influence and eventually overcome the approach tenden-

cies. If tempted to steal, for example, the child may shift attention away from the rewarding object and its associated positive feelings. He or she may amplify conceptual beliefs that it would be bad to steal and good to resist this temptation. The child would also be likely to attend to potential outcomes related to possible actions such as the possibility of being punished or feeling guilty afterward and of feeling proud and competent if the impulse is controlled. Although there are different attentional strategies that can be deployed, the basic idea is to redirect support (exteroceptive, interoceptive, and conceptual informational support) from the dominant to the subordinate motive.

For children with stronger defensive tendencies, the main regulatory challenge will be overcoming their fear and approaching a situation they would rather avoid. Various strategies can again be used, such as reorienting from the threatening aspects of the situation and their anxious feelings to safer aspects and feelings of relief or assurance. Also, the child can call on beliefs about what should be done ("I should be friendly"), what should not be done ("I shouldn't be a coward"), and what can be done ("I can do this"), as well as gain strength by accessing potential feelings of guilt and pride related to avoiding and approaching, respectively. Clearly, such self-control can be extremely difficult for the child, and he or she will often fail. But if adequate representations and attentional skills are available, and if the necessary effort can be sustained, quite difficult forms of coping can be accomplished. As mentioned earlier, children with good effortful control are likely to benefit from their attentional skills.

The most influential research on self-control is that done by Mischel and his colleagues. Working with a delay of gratification task, these researchers demonstrated that the ability to delay depends on various attentional strategies that serve to amplify the "cool" relative to the "hot" aspects of the situation (Metcalf & Mischel, 1999). For example, children are better able to delay eating a marshmallow when they look away from it or think of it as a puffy white cloud. Nor do they want to think about how good it might taste. One of the most remarkable aspects of this research is the apparent stability of the underlying skills. Preschool ability to delay gratification predicts competent coping during adolescence (Shoda, Mischel, & Peake, 1990) and even competent coping with rejection in the early 30s (Ayduk et al., 2000).

Such stability is consistent with the idea that self-control depends on underlying frontal capacities such as attention. Given the importance of attention in motivational functioning and self-control, it seems clear that attention should be a key target of intervention and treat-

ment. Such a focus is evident in pharmacological approaches, though the effect is relatively indirect; for example, various antidepressants and stimulants manipulate the central monoamine systems, which in turn influence frontal functioning. It is also central to cognitive-behavioral approaches, where a main goal is to help the patient to deploy attention in a more voluntary and effective way and thereby to overcome automatic and maladaptive patterns of thought (Wells & Matthews, 1994).

Constraints on Self-Control

Although voluntary self-control is one of our greatest strengths, it is a capacity that is limited in many ways. It depends not only on the child's frontal attentional capacity, but also on the strength of the to-be-regulated motives. In anxiety, for example, there are many reactive components that can constrain self-control. For example, anxiety often involves a strong autonomic response, resulting in intense feelings of tension. These anxious feelings can capture attention, leading to a state of self-consciousness that interferes with other processing (Hamilton & Ingram, 2001; Matthews, 1997). Regarding attention, we have noted that anxiety tends to narrow attention and to impair disengagement (Tucker & Derryberry, 1992). Working together, these reactive elements render the anxious state very difficult to moderate through voluntary attention.

In addition, self-control can be limited by physiological changes indirectly related to frontal attentional mechanisms. Research by Baumeister (e.g., Muraven, Tice, & Baumeister, 1998) has shown that self-control tends to decrease following its exertion, leading to breakdowns in control on subsequent tasks. A simple explanation for such breakdowns is that self-control requires some type of "energy" in the form of neurochemicals that facilitate frontal activity (e.g., dopamine, serotonin). If these substances are limited, then they are likely to become depleted during effortful or prolonged self-control. Alternatively, the depletion could occur within one of the higher-level motivational systems (e.g., defensive), such that the initially controlled system (e.g., appetitive) becomes disinhibited and thus rebounds (Grossberg & Gutowski, 1987). In either case, these types of dynamic fluctuations help explain why a child's symptoms may fluctuate across time, despite changes in external rewards and punishments. The child may initially be able to voluntarily control his or her behavior, but symptoms return as the child's resources are fatigued.

In summary, our discussion of self-regulation has emphasized the idea that motivational systems are complex self-regulating systems. They carry out a rapid reorganization or tuning of the brain, a coordinated and distributed

regulation aimed at promoting a processing state that is adaptive given current motivational needs. The effectiveness of this state in meeting these needs will depend not only on the motivational system itself, but also on the efficiency of the regulated endocrine, autonomic, motor, arousal, and attentional systems. Moreover, because these component systems are shared by other motivational systems, it is necessary to consider interactions between the systems. Whereas some interactions may involve reactive suppression of one system by the other, in conflict situations voluntary self-control can be brought into play. Such voluntary effort provides a form of regulation that goes beyond the influence of the environment and dominant motivational system to provide more effective processing.

When applied to personality and psychopathology, an emphasis on the regulatory nature of motivational systems provides a better understanding of the active and reactive nature of children's coping. Vulnerabilities to externalizing disorders can be seen to arise from multiple sources, such as an overactive appetitive system and underactive defensive system or a weak attentional capacity. Conversely, the problematic coping involved in internalizing behavior can result from overly strong defensive tendencies, weak appetitive motivation, or weak attention. Although voluntary attention can provide highly effective regulation, some attentional strategies are demanding and beyond the child's capabilities. In addition, the child's reactive tendencies may be too strong to constrain, or the attentional capacity itself may weaken across time. As a result, some children may be forced to rely on less efficient regulatory strategies that provide only short-term relief.

Although a regulatory emphasis is helpful in understanding the child's coping efforts, the approach remains limited in accounting for the specific types of impulses or fears that become important in children's personalities. To address such issues of content, it is helpful to step back and adopt a stronger developmental view of motivational systems across time. The development perspective shows that regulatory mechanisms such as arousal and attention are not only designed to modulate ongoing information processing, but in addition, they are designed to modulate the storage of that information in memory. As will be seen in the next section, motivational processes can be viewed as developmental facilitators by functioning to select significant information for storage in memory, information that will guide motivational function in the future. By examining this progressive selection, we can better understand the extent to which the child's personality is "self-organized" and in turn, the varying content of the child's hopes and fears.

MOTIVATION AND SELF-ORGANIZATION

The developing brain is often viewed as a highly plastic organ that receives instructions from the environment. Such a perspective has much to offer, shedding light on the importance of the environment in both adaptive and maladaptive development. However, the brain's regulatory capacity suggests that more than simple environmental instruction is involved. In this final section, we suggest that personality development can also be viewed as a selective process, through which underlying motivational processes select specific types of environmental information to be represented in the brain (Cicchetti & Tucker, 1994; Derryberry & Reed, 1994b). The motivational systems can be viewed as a generative core of the brain: They establish regulatory states designed to promote adaptive sensory-response organization based on the child's needs. Working together with environmental input, these internal selective processes lead to the construction of progressively complex representations of the self and the world. As will be seen, such an approach provides a view of the differentiation that occurs with development, as well as the integrative aspects of self-organization. In turn, examining the differentiation and integration provides a more precise view of the primary symptoms to which children may become vulnerable.

Motivation and Learning

Motivational systems can influence memory in multiple ways. To begin, motives will influence the types of environment to which the child is exposed (Scarr & McCartney, 1983). This can be done at the most general level through regulation of the child's approach tendencies. Children with strong approach motivation are more likely to expose themselves to various types of exciting, novel, and social environments. In contrast, more inhibited children are likely to avoid these environments and to selectively approach less threatening situations. Through such motivated response regulation, children can frequently select the type of environment and information that they learn.

Moreover, even when children are forced to approach a certain environment (e.g., school), motivational differences will be important in regulating what they learn. As describe earlier, a key regulation carried out by motivational systems is that of the multiple arousal systems ascending to the cortex. Much evidence suggests that the relevant neuromodulators (e.g., norepinephrine, dopamine, acetylcholine) are involved in memory, contributing in various ways to the se-

lection of synapses for stabilization in the cortex. Even peripheral arousal mechanisms, such as the hormones cortisol and epinephrine, are involved in consolidation of long-term memory (McGaugh & Cahill, 2002; Schultz, 1998; Singer, 1990). Thus, regardless of the environment, differences in children's motivational and arousal reactions are likely to lead to different memories. Reward-oriented children may show greater arousal following an academic success than failure, leading to a progressive memory structure that emphasizes their previous successes. In contrast, more anxious children should show greater arousal following failure and a corresponding negative memory.

Furthermore, much evidence suggests that attention facilitates memory. The Pearce-Hall (1980) model of classical conditioning proposes that attention must be paid to the conditioned stimulus to allow it to gain or lose associative strength (Pearce, 1987). Models of observational learning also assume that attention is fundamental to the storage of information in memory. Attention may be less important for simple forms of sequence learning, but more complex sequences that involve hierarchical associations do require attention (e.g., Curran & Keele, 1993). Based on these and additional findings that emotional stimuli tend to be preferentially attended, one would expect enhanced memory for emotional stimuli. Indeed, many studies have now shown better memory for simple emotional stimuli compared to neutral stimuli (e.g., Hamann, 2001). Memory also tends to be better for emotional episodes, which may be partly due to the attention allocated during the elaboration and rehearsal of such episodes (Ochsner & Schacter, 2000). Combined with additional findings that certain types of personalities preferentially attend to certain stimuli, one would further expect relations between personality and memory. Consistent with this hypothesis, anxious individuals tend to show preferential attention to and memory of threatening information (e.g., McCabe, 1999; McNally, Lasko, Macklin, & Pitman, 1995; Reidy & Richards, 1997). Thus, personality differences may differentially bias attention and thereby lead to distinct patterns of memory.

If children with strong defensive systems pay more attention to environmental threats, then across time, they are likely to develop strong representations of various types of dangers. These representations may be further strengthened by anticipatory attention when worrying about some danger before it occurs, as well as by elaboration and rumination after it occurs. The resulting representations may be wide-ranging in their focus, but with many tending to pivot around some threatening aspects of the self or other people. For example, some children may

develop elaborate subjective representations of shortcomings in their self-concept, perhaps accompanied by objective representations of the negative ways other people might view them. These types of representations would tend to fuel evaluative fears related to social anxiety. Along related lines, some children may develop strong representations of the sources of safety that help attenuate their fears, representations that tend to emphasize their dependence and reliance on others for security. Such representations may contribute to problems involving Attachment Disorder and school phobia. Other anxious children articulate threat-related representations that are less self-oriented or social in nature. Examples here would be representations related to physical dangers in the environment, such as certain types of animals and heights (Derryberry & Reed, 1996).

Although more longitudinal research is needed, the regulation of arousal and attentional systems should allow underlying motivational systems to progressively construct representations that are relevant to the child's appetitive and defensive needs. This makes adaptive sense in that the motivational systems selectively stabilize information that can enhance their future performance. It is important to note that the developing cortical representations feed back on the subcortical motivational circuits, allowing them to function as cortical or cognitive extensions of the child's motives. In a sense, the more primitive motivational circuitry organizes itself by assimilating the representational capacities of the more advanced cortical architecture (Derryberry & Reed, 1994b; Panksepp, 1998). As discussed in subsequent sections, the representations can serve as more complex recognition mechanisms for predicting and detecting significant environmental events. In addition, the representations can serve to guide the child's behavior by providing navigational markers as he or she attempts to cope with the situation.

Self-Organized Representations

In the discussion that follows, we adopt a broad perspective of cortical representations as rooted in underlying limbic and brain stem circuitry. The representations are highly distributed across the cortex, interconnecting regions that serve exteroceptive, conceptual/episodic, interoceptive, and response processing. Exteroceptive processing is carried out by posterior sensory and association regions, whereas conceptual and episodic memories are focused in posterior and frontal association areas. Interoceptive representations are also located in frontal regions, including the orbital, medial, and insular regions.

Finally, the response-related functions are also frontal, including cingulate, premotor, and motor regions (i.e., the medial and orbital/lateral trends described earlier).

All these regions are extensively interconnected and participate, to varying degrees, in the representational process. One can, of course, focus on more specific representations localized in circumscribed regions, but for personality and psychopathology, the interactions between representational fields is equally important. This notion of distributed representations is illustrated in Figure 12.3.

As connections between exteroceptive and interoceptive regions become stabilized, the child becomes able to relate stimuli to emotional feelings. Many types of emotional representations may be stored in the frontal lobe, but particularly important will be those related to motivational outcomes, that is, whether an appetitive stimulus results in pleasure or frustration and whether a defensive stimulus results in pain or relief. Thus, the exteroceptive-interoceptive connections provide a rapid means of stimulus-outcome evaluation, allowing a direct connection between a stimulus and a specific hedonic outcome. Similarly, connections from conceptual regions to interoceptive regions afford an instantaneous evaluation of ideas, beliefs, and

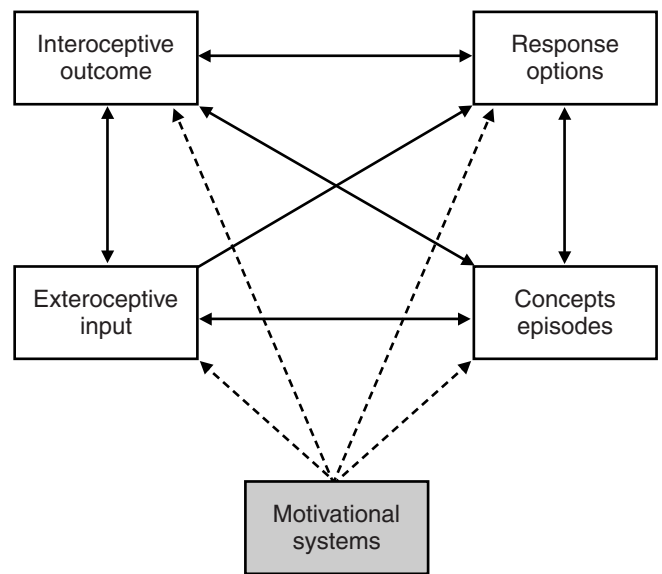

Figure 12.3 Illustration of distributed cortical representations. Information is stored in different cortical regions regarding exteroceptive, interoceptive, conceptual, and response information. In this example, interoceptive information involves hedonic outcomes such as pleasure, frustration, pain, and relief, which can be used in evaluating various sensory and response options. Ascending connections reflect the role of subcortical motivational systems in development and online modulation of representations.

conceptual aspects of the self. As they feed back into the subcortical motivational circuits, such cortical connections can enhance the detection or recognition function of the subcortical systems (Damasio, 1994; Derryberry & Reed, 1994b; Schoenbaum, Chiba, et al., 2003). Finally, connections between motor regions and interoceptive regions afford a rapid evaluation of potential response options, prior to their actual execution. Response selection under appetitive and defensive conditions may thus be biased in favor of responses related to pleasurable and relieving outcomes. These processes will help support the guidance function of the motivational system. To return to Nauta's (1971) seminal ideas, the stimulus-outcome and response-outcome links establish the navigational markers for guiding behavior.

We do not mean to imply that these distributed representations are completely stable or hardwired, for the system must remain plastic and responsive to environmental changes. In addition, the person's internal hormonal and arousal states appear capable of modulating the links among various cortical regions, in a sense reconfiguring the representational network to fit current needs. For example, ascending cholinergic projections preferentially target connections between exteroceptive and interoceptive regions, suggesting that this neuromodulator facilitates stimulus-outcome evaluations. Ascending dopamine projections preferentially target interoceptive and response areas, suggesting that they may facilitate response-outcome processing.

But in terms of personality, the important point is that as the child develops, projections to the cortex will progressively sculpt the representations to support the child's motives. The child's appetitive system will function to tune exteroceptive circuits to many types of rewards (e.g., smiles, food, excitement) that the child experiences. Conceptual and episodic pathways will similarly be molded to represent rewarding information, such as the positive traits of the self, positive aspects of other people, positive events in the past, and positive events in the future. Interoceptive circuitry will be shaped by underlying needs and desires, as well as the outcome states of pleasure and frustration. The response repertoire will accordingly be selected in favor of various approach strategies and actions. In contrast, the child's defensive system will promote cortical representations aimed at detecting danger and guiding avoidance behavior. Exteroceptive regions will be tuned to potential dangers such as sources of pain and disapproval, whereas interoceptive regions will be shaped by experiences of pain, fear, and relief. Conceptual and episodic regions will be shaped to store memories regarding negative traits and

events, and motor pathways will be stabilized that have been successful in avoiding pain and obtaining relief.

When approached in these simple terms, the developmental process and resultant cortical connectivity appear fundamentally adaptive: As their representational capacity becomes more finely tuned, children should become more and more efficient at anticipating and satisfying their needs. Unfortunately, this adaptive process can be undermined in a variety of ways. Because the child's representations are so central to understanding his or her symptoms, we consider these problems in some detail in the next section.

Problems of Representation

A general source of risk involves imbalances in the strength of the underlying motivational systems. In simplest terms, problems can arise because the motivational imbalance biases the representational process in favor of one type of information when, in reality, the world consists of both positive and negative information. Focusing on the self-concept, for example, children with a strong appetitive and weak defensive system may overrepresent their positive attributes and underrepresent their negative attributes. Such representations might be adaptive in motivating the child to approach difficult tasks, but they can also lead to frustration and disappointment when the situation is beyond the child's abilities. As discussed in more detail later, the weak defensive system may also undermine representations important for emotions such as guilt and empathy. In contrast, children with a strong defensive and weak appetitive capacity will tend to develop representations that emphasize their negative attributes and underemphasize positive attributes. Though such humility can have its advantages, these children are likely to suffer in a variety of ways and, at the same time, to blame themselves for their conceived inadequacies. In the worst cases, children may represent themselves not only as negative, but also as powerless in overcoming their shortcomings. These are, of course, highly simplified examples, intended only to establish a general framework for examining more specific representational problems.

The more specific problems can be approached in light of the regulatory functions carried out by the motivational systems. As discussed earlier, the motivational systems function by regulating subsystems controlling autonomic/endocrine activity, central arousal, response activity, and attention (Figure 12.2). Children will vary not only in the reactivity of the central motivational circuits, but also in terms of these subsystems. If one or more of these subsystems

tems is too weak or too strong, the efficiency of the regulation will suffer, and this inefficiency may bias representational development.

For example, some children tend to have particularly strong autonomic reactions, perhaps related to low vagal tone. The autonomic activity is likely to attract attention, leading to representations with strong links between interoceptive information and exteroceptive and conceptual elements. Such an interoceptive emphasis can prove adaptive or maladaptive, depending on the nature of the representation. If an anxious child has a strong autonomic reaction when meeting a new child, attention may become self-focused and the child may lose track of important events in the social situation (Matthews, 1997). This distraction would lead to an impoverished representation of the external aspects of the interaction (e.g., characteristics of the other child), which would in turn impair his or her performance in subsequent encounters. In addition, the strong autonomic activity and self-focused attention could lead the child to make an internal rather than external attribution, blaming the self if the interaction was unpleasant. The idea here is that the focus on the body, as the physical locus of the self, helps establish a stronger link between the negative feeling and the self rather than between the negative feeling and the other child (Dienstbier, 1984).

In other instances, strong autonomic reactions may facilitate more useful representations such as those supporting conscience and moral behavior. Intense autonomic reactions following a transgression may again cause the anxious child to focus on the self, increasing the odds that he or she will make an internal attribution and internalize the relevant moral principle (Dienstbier, 1984; Kochanska, 1997). The intense autonomic reaction makes it easier for the child to link the negative feeling to activated conceptual content (i.e., a moral principle). This could be one of the pathways that contribute to the facilitated moral development and vulnerability to guilt evident in anxious children. In contrast, the absence of strong autonomic reactivity may contribute to impaired moral development evident in psychopathic individuals. This autonomic relation is consistent with evidence that adult psychopaths and children with ADHD and Conduct Disorder tend to show decreased autonomic reactivity (Beauchaine, Katkin, Strassberg, & Snarr, 2001). In some of these children, the inability to generate and experience aversive autonomic activity may contribute to the development of deficient interoceptive markers in their representations. Besides problems in guiding behavior, such representations may lead to deficiencies in moral internalization and emotions such as guilt and remorse (e.g., Damasio, 1994; Nauta, 1971). Functional MRI studies indi-

cate that moral emotions activate orbital and medial frontal networks, along with areas of the superior temporal sulcus (Moll et al., 2002).

A more wide-ranging source of representational problems arises from imbalances in the central arousal systems. As described earlier, ascending projections releasing dopamine, serotonin, norepinephrine, and acetylcholine are recruited in varying combinations during different motivational states. These neuromodulators function to regulate ongoing cortical processing and to facilitate storage of information in memory. To build on the interoceptive example described earlier, cholinergic projections from the nucleus basalis target the entire cortex but are particularly dense in the paralimbic regions that feed into the limbic system. Deficits in acetylcholine have a variety of effects on memory, but from an anatomical perspective, they would likely diminish the interoceptive facets of representations, perhaps promoting deficits in behavioral guidance similar to those with weak autonomic reactivity. In addition, cholinergic deficits could impair connections from the cortical representations to the limbic motivational circuits. Such a disconnection would make it more difficult for the individual to detect a motivationally relevant external or conceptual event, resulting in relatively apathetic behavior (Mesulam, 1988).

Additional representational problems may arise from dopamine imbalances. If dopamine is too low, as appears to occur in ADHD, the child will have difficulty focusing attention on central details of the situation. As a result, his or her representations, in the classroom and elsewhere, may often be missing important central details. In contrast, dopamine appears to be high in certain anxiety disorders, giving rise to narrowed attention and tightly coupled information processing (Tucker & Derryberry, 1992). Such a mode of processing could promote representations that overemphasize central aspects of an episode (e.g., "I was bad"), at the expense of more peripheral but still relevant information (e.g., mitigating circumstances). This is consistent with findings that children undergoing painful medical procedures show quite accurate memory for details, though their memory decreases with the extent of distress (Chen, Zeltzer, Craske, & Katz, 2000). It is also consistent with certain paranoid forms of thought, in which a set of relatively unrelated events are woven together in a tight, inflexible belief system, often with a general neglect of the big picture (Tucker & Derryberry, 1992).

A final source of representational problems arises from deficits in frontal attentional functioning. As described earlier, frontal attentional networks appear capable of constraining more reactive attentional effects elicited by the

motivations. If frontal mechanisms are weak, attention will be driven in a more reactive way by subcortical mechanisms (e.g., overfocusing from dopamine, difficulties in disengaging). In these cases, different types of information may be equally available to the child, but attentional biases would impair the balanced representation of that information in memory. Anxious children with poor attentional control may form episodic representations of social situations that emphasize only the threats (e.g., looks of anger, disapproval). If the child has better control, he or she may be able to disengage from the threats and take advantage of other information (e.g., looks of reassurance, support). The resulting representation that related safety to other people and behaviors would help in guiding their future social interactions toward relieving outcomes. Without such control, the child's representations are likely to emphasize threat, thus making it easier for the child to worry about threat and to expect threat in a social situation (i.e., to be more socially anxious). On the other hand, it is also possible that some anxious children with poor attention may come to focus very strongly on a source of safety in a threatening situation. A young child may form representations that emphasize the presence of the parent, and older children may emphasize their friends as sources of support and reassurance. If the representations are imbalanced to the extent that the child relies too heavily on others, then symptoms related to dependency and attachment problems might be supported. Because coping responses are linked to another person instead of the self, the child lacks a sense of agency and control when the source of support is not present (Derbyberry & Reed, 1994b).

More generally, it's worth noting that social situations involve rather subtle and fast-moving events, requiring attentional shifts from one's feelings, to what one wants to say, to what the other is saying, to what the other might be thinking, and so on. Even for a child with relatively good attention, it is fairly easy to become overloaded in social situations (Rapee & Heimberg, 1997). If attention cannot keep up with the pace of the interaction, or if it becomes inappropriately focused on the self, a good deal of information relevant to both threat and safety is likely to be missed. The consequent representation will be impoverished and of limited help in guiding future social performance. Links between attentional control and social competence have been demonstrated in the work of Eisenberg and her colleagues (2000).

Similar effects of attention can be seen in conceptual and episodic representations of the self. Many anxious children are likely to preferentially attend to the more

negative components of their personality, leading to an overemphasis on negative rather than positive traits. Similarly, reward-oriented children are likely to develop self-representations that emphasize their positive attributes. Adult studies suggest that some individuals tend to interlink self-related traits into relatively separate positive and negative structures, creating a compartmentalized form of representation (Showers & Kling, 1996). Such representations are likely to become problematic for children with poor attentional control: Spreading activation within the negative compartment would lead to increasing feelings of worthlessness of the anxious child, perhaps promoting the global forms of attribution evident in some anxious and depressed individuals. The compartmentalized situation may seem better for the appetitive child, but even here, the spreading activation could lead to overconfidence, grandiosity, and poor decisions. In contrast, children with good control of attention could inhibit this spreading activation and may compensate by shifting attention from a bad trait to a good trait ("I'm bad at math but good at spelling"). This type of cognitive coping strategy would be likely to lead to an integrative self-organization (Showers & Kling, 1996). As the integrative organization develops, anxious children will be better able to attenuate their self-related fears by focusing on their positive traits, and impulsive children will be better able to constrain their grandiosity by focusing on their negative traits. Neuroimaging studies suggest that episodic and semantic information regarding the self activates circuitry in anterior, polar regions of the frontal lobe (Craik et al., 1999).

Although more research is necessary, we suspect that in the long run, representations that are relatively balanced in terms of positive and negative components will serve a protective function for many children. As described earlier, representations can become imbalanced if one motivational system tends to dominate the other, or if components within the systems, such as autonomic, arousal, and attentional activity, are overly strong or weak in the system as a whole. Even given such imbalances between and within the motivational systems, the possibility remains that children with good attention may be able to exert effort and restore more balanced and objective representations.

Environmental Influences

So far, our discussion of self-organization has focused on the development of the representational functions of motivational systems. We have suggested that representations may

be related to specific symptoms, which arise from the balance between the two motivational systems and the functioning of components within the systems. The major limitation of this approach arises from its emphasis on internal at the expense of external environmental influences. It is clearly beyond the scope of this chapter to discuss the countless ways the environment influences self-organization. What we hope to provide instead is a general framework that organizes environmental influences into a set of domains that are particularly important to personality organization. These domains include environmental influences related to social inclusion, social status, achievement, morality, and intellectual development.

A second shortcoming involves our emphasis on two motivational systems and a small set of emotions (fear, hope, relief, frustration, pride, guilt). Although such a simple approach provides a useful starting point, it fails to explain a wide range of more complex human motives and emotions. It is worth emphasizing that future advances may delineate additional, distinct circuits related to more specific motives and emotions. In the mean time, however, it is worthwhile to examine the extent to which such emotions can be generated through a differentiation of our basic motivational systems. Therefore, in considering the different environmental domains through which children develop, we also examine the possibility that these domains allow a differentiation of basic appetitive and defensive motives into more specific motives related to more complex emotions.

In a sense, we are adopting an inside-out approach to the environment, attempting to organize environmental influences in terms of their relevance to internal motivational and developmental processes. As will be seen, the emotional and motivational consequences of each domain can be viewed in terms of internally generated appetitive and defensive processes. At the same time, the domains are characterized by distinct external incentives. It is assumed that the strengths of these incentives will differ across children, resulting from values of their family, their educational opportunities, and so on. As a result, children's appetitive tendencies may differentiate along various pathways, depending on the availability of these various incentives. Some children may develop extensively in areas such as social inclusion and morality, and others in areas such as social status and achievement. If development is frustrated in one of these domains, the child may select another domain that better fits his or her motivational goals and efficiency. This general process is illustrated in Figure 12.4.

Many theorists have emphasized the caregiver and early attachment relationship as fundamental to social de-

velopment. Although this vast literature is beyond our scope, attachment theorists have proposed that representations of the self and the self in relation to another person can be strongly influenced by the quality of the early caregiving matrix (e.g., Bowlby, 1988). The most severe disruptions in this initial environment arise in cases where children are physically abused, sexually abused, or neglected. When studied using narrative story stems, maltreated children have been found to reflect more negative representations of the self and also the mother (Toth, Cicchetti, Macfie, & Emde, 1997). Interestingly, no differences were found in positive representations between maltreated and nonmaltreated children, a finding consistent with the notion that representations may be shaped by separable motivational systems. In addition, longitudinal work suggests that the negative representations of maltreated children tend to coalesce and consolidate as development proceeds (Toth, Cicchetti, Macfie, Maughan, & VanMeenan, 2000). Furthermore, several investigations indicate that maltreated children tend to generalize their negative representations, making them vulnerable to future relationship problems (e.g., Lynch & Cicchetti, 1991). Clearly, representations of the self and others appear to be highly sensitive to the early caregiving environment and thus constitute an important target for intervention.

A related environmental domain involves social groups. From an evolutionary perspective, crucial resources and protection can be gained or lost depending on whether one is included in or excluded from a group. Thus, it is not surprising that the hope for acceptance and the fear of rejection are two of our strongest social motives. Social environments differ in their potential for acceptance and rejection, and children are differentially sensitive to these two outcomes (Gazelle & Ladd, 2003). As a result, children develop representations of the self, of others, and of the self in relation to others that help them navigate the social world. Whether the self is represented as acceptable or unacceptable and whether others are viewed as accepting or rejecting will be central to the child's personality (Asher & Paquette, 2003; Gazelle & Ladd, 2003; Leary, Tambor, Terdal, & Downs, 1995). When accepted, children will experience positive feelings related to affection, belongingness, and support. If rejection occurs and is internally attributed, then feelings of rejection, loneliness, anxiety, and sadness are likely. For children initially prone to aggression, early rejection can exacerbate antisocial development and more resentful and hostile emotions (Dodge et al., 2003).

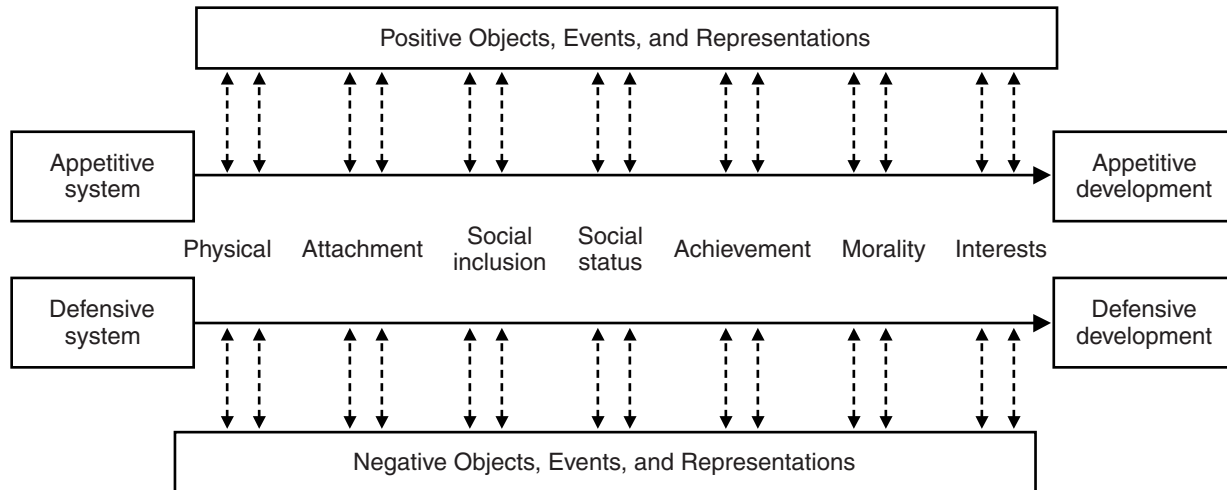

Figure 12.4 Illustration of interaction between developing motivational systems and the environment. Environment refers to objects, events, and related concepts in physical, social, achievement, and moral domains. Each domain is capable of providing various rewarding or punishing inputs to the appetitive and defensive systems, as a result of which the motivational systems facilitate and form connections with representations of domain-related objects and events. Dotted lines reflect potential branches of the motivational systems within the environmental domains.

Related to social inclusion are environmental incentives involving social status (e.g., popularity and dominance). Varying emphases on status appear in different families and peer groups, and again, children are more or less sensitive to such matters (Lease, Musgrove, & Axelrod, 2002). Whether children represent themselves and others as superior or inferior can have strong impact on their self-evaluation and treatment of others (Leary et al., 1995). On the emotional side, status representations focusing on the self can generate feelings such as pride, superiority, inferiority, and shame. When focused on others, status representations can generate feelings of respect or disrespect. Again, such representations of self and others can have potent influences on interpersonal behavior.

Another crucial domain is that of achievement, encompassing environmental events ranging from tasks around the house, to skills in games and sports, to academic performance. Motivational approaches to achievement have long emphasized the relative strengths of motives to approach success and to avoid failure (Atkinson, 1983). More recently, the child's fear of failure has been dissociated into a more active form of defensive approach along with the avoidance of achievement contexts (Elliot & Church, 1997). Although such models fit well with appetitive and defensive motivational systems, it is clear that different families, peer groups, and cultures put varying emphasis on achievement. As a simple example, parents set different standards for successful academic performance, requiring A's, B's, C's, and in some cases even less. It is natural for

the child to internalize these standards and to use them in self-evaluation. Whether the child represents the self as a success or a failure will have potent motivational and emotional consequences. On the motivational side, the representations will be crucial to the child's sense of self-efficacy and perceived control (Skinner, Zimmerman-Gembeck, & Connell, 1998). On the emotional side, the child may feel incompetent and ashamed given failure but competent and proud given success.

For some children, a particularly central domain will be the moral domain. Here, we simply refer to the environmental rules about what is right and wrong, as transmitted through the child's parents, peers, and belief systems. The appetitive motivation may vary from simply hoping to being a "good" person to the hope of religious salvation. The defensive component may promote a fear of being "bad" and even religious damnation. Again, there will be wide-ranging differences in the ethical standards to which children are exposed. Like the achievement-related representations, those in the ethical domain come to constitute important standards in evaluating the self and others. Whether children view themselves and others as good or bad will have a strong impact on their private and social experiences. Relevant feelings include those of righteousness, virtuousness, guilt, and shame. In regard to others' morality, emotions such as admiration, approval, condemnation, and contempt may come into play.

A final domain entails the more abstract intellectual realm that becomes important for older children and ado-

lescents. Rather than centering on other people, achievements, and ethical standards, this is in many ways a more open domain involving the primarily appetitive pleasures that can be derived from the manipulation of ideas. The domain may begin with simple intellectual activities such as fantasy, reading, and hobbies and expand into more complex philosophical, scientific, and aesthetic interests in some children. Again, there are enormous differences in the intellectual environments to which children are exposed. To the extent to which they develop, intellectual pursuits provide perhaps the most subtle forms of emotion, such as the curiosity and sense of wonder about what is unknown, the intellectual pleasures that arise from acquired understanding, and the aesthetic pleasures that arise from art. Although we have emphasized the appetitive side of the intellectual domain, beliefs can certainly be used for defensive purposes. Typical examples are an anxious or mistreated child's retreat into a fantasy world, or adoption of a strong religious belief as a source of relief and solace.

The grouping of environments into more simple domains provides a view of how relatively simple motivational systems may differentiate along different pathways to generate more complex representations and emotions. The nature of the domain will determine the type of exteroceptive, interoceptive, conceptual, and response information that compose the child's representations. Given that these pathways differ in their availability across children, such an approach also helps highlight the different trajectories along which personality may self-organize. Thus, different children's underlying appetitive and defensive tendencies may differentiate in distinct branching patterns related to acceptance-rejection, superiority-inferiority, success-failure, and pride-guilt. To better understand the child's symptoms, more research needs to focus on these branches and, eventually, on the individual twigs along them.

In addition to clarifying the differentiation that occurs with personality development, an emphasis on environmental domains provides a view of the integrative processes at work in self-organization. On the one hand, we have already emphasized the extent to which the child's cortical representations are vertically integrated: They are fundamentally rooted in subcortical limbic and brain stem structures. However, once the cortical branching in environmental domains is considered, we can see another form of organization, within which the differentiated motives function together to support one another. In other words, these domains are highly complementary and can thus facilitate one another.

For example, a child with high status (e.g., popularity) in one group will have an easier time being accepted into a

new social group. In addition, both achievement and ethical success can support inclusion and status; that is, children who are competent and ethical are most likely to be accepted and attain status in a group. Similarly, development in the intellectual domain can facilitate the child's potential in achievement and ethical domains, as well as in inclusion and status domains. Thus, not only are there many different branches along which children can develop, but many of these branches can grow together to support one another.

In addition to this supportive function, the different domains can substitute for one another in satisfying the child's needs. If development of a motivational system is suppressed in one domain, it is likely to develop in another. A child who is unsuccessful in academics may satisfy his or her hope for success in athletics. A child who is generally unsuccessful in the achievement domain may turn to ethics or status to satisfy appetitive needs. From this perspective, self-organization is similar to an evolutionary process in that a wide variety of environmental or representational niches are available for motivational development. Although children may have problems in some areas, it seems unlikely that the self-organization process will be blocked or disrupted. Rather, it will tend to develop along a different trajectory, taking advantage of the niches that are available. When viewed in this way, a clear distinction between normal and abnormal development becomes more difficult to make. As Fischer et al. (1997) point out, psychopathology can be viewed as adaptive development, albeit along distinctive pathways.

FUTURE DIRECTIONS

Although much progress has been made in understanding the general functioning of regulatory processes, it is clear that we are only beginning to appreciate their complexity. Greater understanding will require research in a number of directions. One of the most important directions will approach motivational functions in light of the broader regulatory systems within which they are embedded. Our treatment here has focused on regulatory subsystems as outputs of the motivational systems, physically adjusted in light of significant inputs. However, these regulatory systems are affected by additional biological influences, such as biological rhythms and states, causing them to vary through tonic states that are to some extent independent of the motivational influence. Moreover, the regulatory systems are widespread in their effects, feeding back to modulate the motivational and attentional systems (e.g.,

Derryberry & Tucker, 1991; Herbert, 1994). As we learn more about this modulation, models will allow more dynamic views of how motivation might be influenced by fluctuating arousal, hormonal, and health states.

A major influence on motivational and attentional systems arises from converging arousal systems employing serotonin, norepinephrine, and dopamine as neuromodulators. These systems are currently manipulated in pharmacological treatments of attentional, anxiety, and depressive disorders. Although such treatments often provide relief, it is fair to say that the underlying mechanisms are poorly understood and that the advisability of manipulating arousal systems in children is questionable. Thus, more research is needed on these systems, particularly regarding their specific functions, their development across time, and the effects of manipulating this development pharmacologically.

At a broader level, future research will explore the extent to which motivational, attentional, and arousal systems are embedded in a modulatory influence arising from the peripheral endocrine system. For example, circulating cortisol released from the adrenal gland appears to interact with central circuits related to anxiety and arousal, possibly potentiating fear reactivity across relatively long time frames (e.g., Gunnar, 1994; Schulkin, Gold, & McEwen, 1998). Similarly, circulating testosterone appears to play a role in potentiating aggressive behavior. Primate research suggests that offensive forms of aggression are related to high plasma testosterone and low cortisol, whereas defensive aggression involves high cortisol (Kalin, 1999).

At an even broader level, much evidence suggests that the peripheral immune system is also capable of adjusting central motivation and arousal (Maier & Watkins, 1998). For example, cells of the immune system release many types of cytokines, some of which (the interleukins and interferons) interact with brain stem circuitry to produce "sickness behavior." This is an organized motivational state characterized by fever, fatigue, immobility, and social withdrawal, presumably designed to complement other components of the immune response (Dantzer et al., 1998). Some researchers are pursuing relations between sickness behavior and depression, attempting to establish basic links between peripheral health and central motivational and psychiatric states (Hickie & Lloyd, 1995).

As we learn more about endocrine and immune effects on the brain, theories will come to appreciate the extent to which motivation is embodied, that is, embedded within and shaped by the body's major regulatory systems. Such theories will deepen our understanding of the difficulties involved in voluntary self-regulation and, when applicable, open up a variety of peripherally focused treatment options.

Along with this emphasis on peripheral influences, future research will continue to focus on the central motivational systems themselves. A particularly important line of research will investigate additional systems besides the general appetitive and defensive systems emphasized here. Panksepp (1998) has provided a valuable start in this direction, describing systems related to exploration, fear, anger, sadness, and affiliation. We suspect that systems related to nurturant and affiliative motivation may prove central to personality and psychopathology (Depue & Morrone-Stupinsky, in press; MacDonald, 1992). Variability in such systems contributes to the major trait dimension of agreeableness. Children with stronger nurturant tendencies are likely to show behaviors such as trust, empathy, and kindness. Such prosocial behaviors will be less common in children with weaker tendencies.

It is relatively easy to see how affiliative/nurturant tendencies might interact with other motivational tendencies. For example, deficiencies in nurturant tendencies, when combined with strong appetitive or weak defensive tendencies, may help to explain the more callous and aggressive forms of conduct problems. Perhaps more intriguing is the regulatory potential of nurturant motivation. Although speculative, it is worth noting that parental behavior, which reflects nurturance at its most extreme, often involves very strong suppression of "selfish" needs as the parents attempt to provide resources and protection for their children. The fact that such behavior is seen across the animal kingdom suggests a powerful form of self-regulation with very deep roots. Studying the development of nurturance should provide new insights regarding self-regulation and its failures.

In addition to investigating new motivational systems, future research will attempt to further differentiate the existing systems. We have tried to give several examples of how the defensive system might eventually come to be understood as a set of interacting subsystems. One approach arose from the notion of vertical integration, within which one can identify primitive brain stem fear mechanisms, anticipatory limbic-related anxiety capacities, and the more abstract conceptual fears afforded by the cortex. Although we emphasized the functional integration across these defensive systems, the hierarchically organized subsystems remain separable, suggesting that imbalances at different levels may give rise to different forms of fear and anxiety. As mentioned earlier, more primitive subsystems may contribute to certain types of panic and depressed feelings, whereas imbalances at the higher levels may move the child toward anticipatory forms of anxiety (e.g., Gray & McNaughton, 1996).

Along with such vertical differentiation, future research will provide new views of the extent to which the defensive system is laterally differentiated. Our earlier example focused on the idea that vulnerable children may develop different forms of anxiety depending on their environments. As illustrated in Figure 12.3, a general fear system may develop a variety of branches related to fears of injury, rejection, achievement, and so on. Although we described such fears as a result of selection within a general defensive system, future research may well discover that these and other fears reflect activity in distinct anxiety-related systems. In other words, there may be 10 specialized anxiety systems within the brain, which tend to covary in the individual because they are all influenced by common regulatory systems (e.g., serotonin, cortisol). To the extent that such separable systems can be isolated, we will be better able to predict children's specific vulnerabilities and alleviate them in a precise manner.

Beyond the motivational systems, future research will extend our understanding of higher-level regulatory mechanisms involved in cognition. The research described here has spoken in relatively general terms, such as attention and arousal, though we have at times alluded to other executive functions. One of the challenges of future research will be to specify the basic cognitive operations related to attention, such as the capacity to monitor action and detect errors, to inhibit dominant response tendencies, to inhibit conceptual pathways, to activate conceptual pathways, to hold and operate on information in working memory, to voluntarily retrieve information from long-term memory, to manipulate mental images, to produce internal speech, and to plan. Again, an important issue will be the extent to which these frontal operations vary independently, or whether they tend to cohere as a function of frontally projecting dopaminergic constraints.

A closely related research area will assess how motivational states may differentially bias these executive processes. Motivation has traditionally been viewed as a descending influence that serves to potentiate relevant response options, such as the freezing, fleeing, or fighting options relevant in a dangerous situation (Gallistel, 1980). However, it is also possible to view motivation as exerting an ascending cortical influence that serves to potentiate sets of cognitive operations (e.g., error detection, conceptual inhibition, short-term memory facilitation) that are adaptive given the information-processing requirements of the ongoing state. Some types of anxiety, such as social anxiety, may facilitate conceptual pathways involved in self-evaluation and error detection, such that individuals tend to "search" for aspects of their behavior that might

lead to rejection. Other types of anxiety may limit conceptual processing while facilitating anticipatory processing, thus allowing the person to better anticipate potential threats in the future (Tucker & Derryberry, 1992). It can be seen that individual differences in the capacity for anticipatory or self-referential processing may bias a child toward different forms of anxiety.

Given this type of functional understanding, future theorizing may shift from the current focus on motivational processes to models that place equal emphasis on variability in children's patterns of cognitive skills. Such models should prove valuable from a developmental perspective because they allow motivation and personality to be linked more directly to the development of specific cognitive skills. A well-known example is the progressive control over impulsive tendencies afforded by the development of internal speech. More recently, Posner and Rothbart (1998) have attempted to trace the development of attentional subsystems and their consequences for emotional development. Moreover, models emphasizing cognitive skills along with motivational tendencies should prove particularly valuable in the study of developmental psychopathology. By incorporating more individual difference variables and examining these variables in various combinations, such models will provide greater resolution in predicting a child's unique vulnerabilities. It may turn out that some cases of childhood anxiety are primarily rooted in an overreactive defensive system, whereas others arise from executive deficits such as poor short-term memory or conceptual inhibition.

Another promising aspect of such a hybrid motivational-cognitive model is that the relevant skills can be assessed longitudinally. If vulnerabilities are detected, prevention techniques can be implemented aimed at strengthening the problematic skill area. For example, various types of mental exercises, ranging from meditative to game-like techniques, can be employed to strengthen relevant systems or skills. Such techniques are already being developed to improve attention (e.g., Wells & Matthews, 1994), and we suspect that other executive processes can also be enhanced. It is worth noting that progress in computer science will lead to increasingly realistic and enjoyable simulations that might be used to exercise relevant brain regions. At the same time, developments in brain imaging will make it increasingly possible to monitor the efficacy of such interventions.

SUMMARY AND CONCLUSIONS

We have described an approach to personality and psychopathology that emphasizes internal biological processes. We began with the idea that the brain is organized around

two basic motivational systems related to appetitive and defensive needs. The motivational systems can be viewed as relatively primitive coping systems, usually functioning in a reactive way but also capable of voluntary functioning. The coping function is accomplished by means of the coordination of other brain systems underlying endocrine, autonomic, motor, arousal, and attentional functions. The consequent motivational state accomplishes two adaptive goals: First, it modulates ongoing information processing to facilitate appetitive and defensive goals; second, it modulates memory storage so as to optimize its functioning in the future. Across time, the motivational states gradually shape the connectivity within the forebrain, guiding a progressive process of personality development and self-organization. This process of self-organization, through which the motivational systems unfold in terms of selected representations, are highly sensitive to the environment, such that different personalities self-organize along diverse pathways.

This view of development provides an especially rich approach to personality. It begins with a focus on individual differences in the relative strengths of the appetitive and defensive systems. This focus provides a general view of personality traits such as extraversion and neuroticism but has difficulty predicting more specific traits and behaviors. This shortcoming can be attenuated by considering individual differences in the component systems related to endocrine, autonomic, motor, arousal, and attentional regulations. In particular, we have tried to point out that it is not simply the strength of the motivational state that is important, but also the efficiency with which the components function. If one or more components are out of balance (e.g., too weak or too strong), the resulting motivational state will tend to be less efficient. Still, such a view remains relatively silent regarding the specific experiences and symptoms evident in different children. To better understand these symptoms, it is crucial to examine the environment in which the child develops. We have suggested that the child's motivational systems will branch within the cortex, establishing representational extensions that are in large part dependent on the environment.

In terms of psychopathology, an implicit assumption is that the problems faced by most children and adults fall within the normal realm of personality. In some cases, symptoms arise because the child is prone to extreme or intense motivational functioning, and in other cases because the regulatory processes are ineffective. Again, we find it useful to view these motivational systems as coping systems, shaped through evolutionary history to enable our species to cope adaptively. The modern world is complex,

however, and children differ in the coping resources (e.g., attentional skills, supportive representations, supportive environments) that are available to them. As a result, children differ dramatically in the efficiency of their coping efforts, and thus in their vulnerability to psychopathology.

An underlying theme of the chapter has been that attention, in particular the frontal systems related to voluntary control, is critical to the child's vulnerability. Indeed, much research suggests that good attention can serve to reduce the child's vulnerability to both internalizing and externalizing disorders. We should emphasize, however, that attention is still poorly understood and is by no means completely separate from other regulatory mechanisms such as arousal. In addition, other executive skills are likely to be important to motivational functioning. As we gain better understanding of how the different regulatory and executive systems work together during various motivational states, we hope techniques will be developed that provide children with greater capacity for self-control.

Although we have consistently emphasized regulatory systems, we should end by noting the importance of the child's representations and the environment. A child might have exceptional attentional control, but in the absence of the appropriate environmental stimulus or internal representation, that attentional control is not going to be that helpful. Children must learn what to attend to in different situations, and moreover, they must have the knowledge or representations that can serve as the objects and guides of attention. Fortunately, by viewing psychopathology in relation to normal personality, we have a fairly direct way of discovering which types of representations are likely to be adaptive in helping the child to cope.

Finally, we would emphasize the child's representations as being particularly important in the study of psychopathology. The child's representations provide the most direct source of his or her experience. To really understand the child's problems, it seems that in many cases, the most useful perspective is one that focuses on the child's personal experiences, that is, how different feelings emerge in relation to different external stimuli, different thoughts, and different response options. If we can better understand the ways the underlying representations are motivated, they will become all the more useful in diagnosis and treatment.

Maladaptive responses to stress are components of both the etiology and expression of many psychiatric disorders (e.g., Dawes et al., 1999). In addition, individuals differ in their stress vulnerability, with some seeming to thrive despite the odds and others succumbing to even relatively mild adversity (Masten, 1999). Early adverse experiences likely contribute to both individual differences in stress vulnerability and their expression in psychiatric disorder (Heim, Owen, Plotsky, & Nemeroff, 1997). Explicating these individual differences and their role in psychiatric etiology is one of the central issues in developmental psychopathology. The goals of this chapter are to describe the current state of our knowledge regarding the developmental neurobiology of stress, its relation to psychiatric disorders, and the impact of early adverse experiences on stress vulnerability

This work was supported by the National Institute of Mental Health “Early Experience, Stress, and Prevention Science” research network (MH60766) and a National Institute of Mental Health Research Scientist Award (MH00946) to the first author and National Institute of Mental Health (MH59396, MH01-0328) and National Institute of Child Health and Human Development (HD/DK37431) grants to the second author.

and resilience. We focus on studies of the limbic-hypothalamic-pituitary adrenocortical (LHPA) system, a critical system fostering both resilience and vulnerability to stress in animals and humans. Research on this neuroendocrine system has a long history.

HISTORICAL OVERVIEW

In 1957, Levine (see review, in press) published a landmark *Science* paper demonstrating that removing rat pups from their mother for a few minutes daily during the first weeks of life permanently reduced activity of the LHPA system. This publication followed one from the previous year demonstrating that this *handling* manipulation also reduced fearful, anxious behavior. The half-century since these publications has seen remarkable advances in preclinical (animal) research on stress and early experience (see Levine, in press). This work built on insights into stress physiology that began with Cannon (1914) and Selye (1936) and took on new meaning with Harris’s (1948) work showing that the brain controlled endocrine activity, including that of the

pituitary-adrenocortical system. More recently, McEwen's (e.g., McEwen, Weiss, & Schwartz, 1968) evidence that glucocorticoids (GCs; cortisol in humans and nonhuman primates, corticosterone in rats), the hormonal products of the LHPA system, both sustain normal brain function and paradoxically endanger nerve cells, ushered in heightened awareness of the critical role of this neuroendocrine system in psychiatric health and disease.

Our understanding of the role of GCs in shaping the developing brain has been enriched through evidence that they contribute to the regulation of brain-derived neurotropic factors (Smith et al., 1995), up-regulate activity of the amygdala (Makino, Gold, & Schulkin, 1994), and target prefrontal systems involved in stress and emotion (Sullivan & Gratton, 2002). Meanwhile, research by Meaney (e.g., Weaver, Cervoni, Diorio, Szyf, & Meaney, 2001), among others, has explicated some of the molecular processes through which early experiences may produce their lifelong effects on stress neurobiology. Critically, in rodents it appears that these molecular processes are set into motion by maternal behavior (see Cirulli & Alleva, 2003).

GCs are only part of the picture. A critical link to psychopathology came with awareness that corticotropin-releasing hormone (CRH), the major LHPA activating hormone in the hypothalamus, also has neurostimulatory and neuromodulatory effects in many regions of the brain involved in stress and emotion (e.g., Heim et al., 1997). When produced and acting outside the hypothalamus, CRH has been shown to play a role in a variety of psychiatric conditions, most principally affective disorders (see Nemeroff, 1996). CRH acts through a family of receptors that mediate different components of behavioral and physiological responses to stress. The development of this receptor system may be another key to how experience shapes stress vulnerability and resilience (reviewed in Heim et al., 1997). Thus, as Levine (in press) noted, what began as a story about the role of GCs in stress regulation may eventually extend into many areas of pathophysiology that are not associated with regulation of the LHPA system.

The history of any field rests on both conceptual and methodological advances. Conceptually, evidence that the stress-emotion system is highly plastic during development and that parental care shapes its development forms the basis for translation of the preclinical work into research on developmental psychopathology. Technically, the critical advances are legion, encompassing much of the armamentaria of modern-day neuroscience (e.g., cloning,

knock-outs, neuroimaging). All of these advances are essential for understanding the processes that transduce experience into altered stress vulnerability, yet advances in the translation of preclinical and neuroscience research into the field of human developmental psychopathology rests on something much more mundane: spit.

Initial measures of adrenocortical activity were indirect and crude (Levine, in press). The development of competitive binding assays allowed measurement of GCs in urine and blood, thus permitting study of the adrenocortical system in humans. Soon after competitive binding assays were available, the first studies of GCs in children appeared (for review, see Gunnar, 1986). However, the immense challenge of collecting urine reliably and the invasiveness of plasma sampling limited the studies that could be conducted on children (reviewed in Gunnar, 1986). Then, in the early 1980s, assay techniques were refined to allow the measurement of cortisol in small amounts of free-flowing saliva (Riad-Fahmy, Read, Walker, & Griffiths, 1982). Salivary cortisol reflects the unbound or biologically active fraction of the hormone and is highly correlated with plasma cortisol concentrations (see Kirschbaum & Hellhammer, 1989, 1994). With the use of salivary cortisol measures, the number of publications on children has increased from fewer than a dozen in the 1970s to nearly that many each month in the first years of the twenty-first century.

The emergence of a developmental systems perspective in child psychology and developmental psychopathology (e.g., Cicchetti & Tucker, 1994) has also encouraged hormone-behavior studies in children. According to this perspective, development involves complex, bidirectional flows of influence across hierarchically organized systems and subsystems, from the level of the gene to the level of social systems. This approach permits inclusion of biological measures in developmental research without implying that behavioral development can be reduced to biological explanations. Nonetheless, these perspectives are not theories and do not provide theory-driven predictions about how physiological measures should be related to behavioral outcomes. Such focused predictions need to be derived from specific models pertaining to the behavioral and biological systems under study.

Recently, investigators have called for more theory-driven studies of cortisol-behavior relations in human developmental research (e.g., Granger & Kivlighan, 2003). Although laudatory, attempts to predict activity of the LHPA system in human development will be problematic as long as most studies of children are restricted to assess-

ing only one level (the adrenal) of this very dynamic, self-regulating system (Gunnar & Vazquez, 2001). One goal of this chapter is to discuss the complex, multifactorial regulation of the LHPA system and to clarify why testing theory-driven predictions requires probing levels of the axis above the adrenal, up to and including corticolimbic pathways into the LHPA system. Because we are limited in our ability to do this kind of research in children, theory-driven research on the LHPA system requires close integration of human developmental research with preclinical animal studies. Theory-driven work in human development also benefits greatly from studies of clinical populations, including adult populations, in which it is ethical to use pharmacological probes and more invasive sampling techniques.

Another stumbling block to theory-driven developmental psychopathology research on the LHPA system has been the lack of criteria for defining and assessing dysregulation. As we will see, most of the studies of children involve assessment of GC levels and GC change or responsivity scores. In addition, there is a growing body of literature on the daily or circadian pattern of GC production. If children with behavior problems and/or adverse early histories exhibit levels, responses, or circadian patterns in GC production that differ from children with fewer behavior problems or less adverse histories, the temptation has been to describe the differences as a reflection of dysregulation of the LHPA system. However, the system might merely be acting differently along some parameter(s), though not be *dysregulated*. Derived from arguments made by Siever and Davis (1985), dysregulation in many physiological systems can be conceptualized as persistent disturbances *in one or more* of the system's homeostatic regulatory mechanisms. We discuss the specific mechanisms later in the chapter, but the observed phenomena indicative of dysregulation can be listed here: (1) Basal output is more erratic; (2) normal periodicities are disrupted; (3) efficiency of feedback mechanisms is increased or decreased, resulting in overly rapid or overly slow return to set points following perturbation; (4) adjustment to repeated stimulation fails; and (5) clinically efficacious treatments restore efficient regulation. Although few studies of children provide enough information to determine whether the LHPA system is dysregulated in relation to either behavior disorders or adverse experiences, preclinical studies do allow such assessments, as do some of the studies of adults that we consider.

In what follows, we provide an overview of the neurobiology of the mature LHPA system and its role in stress and adaptation. We then describe the developmental neurobiology of the system based on preclinical research, with links to human development when feasible. Next, we examine associations between LHPA activity and psychopathology in children as a prelude to examining the role of experience in shaping the activity of the LHPA system in animals and humans.

THE MATURE LIMBIC-HYPOTHALAMIC-PITUITARY-ADRENOCORTICAL SYSTEM

The LHPA axis is the classical stress system (Selye, 1936). Once labeled the HPA axis, an L for limbic is now commonly added to indicate the critical role of the limbic system in its activity. Two molecules at the opposite ends of the activating pathway regulate LHPA activity: CRH and GCs. CRH activates both hormonal and behavioral stress responses (e.g., Heim et al., 1997). CRH-stimulated behaviors include heightened vigilance, defense-related learning and memory, and context-dependent motor responses: freezing, fighting, or fleeing. Activation of the LHPA axis leads to increases in GCs, extremely potent steroids that function to facilitate adaptation and to restore homeostasis through changing internal dynamics. McEwen (1998) has described this dynamic regulation as *allostasis*, or the maintenance of stability through change. The capacity of organisms to make allostatic adjustments is necessary for survival. However, the biological processes set into motion are meant for short-term adaptations and are potentially damaging to physical and mental health if they persist too long or occur too frequently. The cost of allostasis has been described as *allostatic load*.

GCs orchestrate allostatic adjustments by operating on the DNA to activate, enhance, or inhibit the gene transcription in most organs and tissues of the body (Sapolsky, Romero, & Munck, 2000). In the periphery, among other actions, GCs promote glycolysis, a process that provides glucose from hepatic stores and facilitates increases in oxygen levels. In the brain, GCs help orchestrate motivation, reward, and mood (de Kloet, 1991). Brief and controllable stress with high but controllable GC levels stimulates exhilarated mood and health-promoting actions. In contrast, as first described by Selye in 1936 (see Table 13.1), prolonged, uncontrollable, or chronic states of distress leading to high or prolonged GC levels can have deleterious mental and

TABLE 13.1 Behavioral and Physiological Adaptations of Acute Stress

Physiological Responses: Redirection of Function	Behavioral Responses: Redirection of Behavior	Physiological Outcome: Redirection of Energy	LHPA Hormone
Increased respiratory function	Increased arousal, vigilance, and attention	Oxygen shunted to CNS and critical body sites	CRH
Increased cardiovascular tone	Increased cognition		GCs
Increased gluconeogenesis; increased lipolysis	Suppression of feeding	Increased body temperature; suppressed appetite	CRH
		Glucose and nutrients shunted to CNS and critical body sites	GCs
Inhibition of growth and reproductive hormones, inflammatory processes, immune system	Suppression of sexual behavior	No reproduction; decreased immune function	CRH and GCs
Limitation of stress (LHPA) activation/ response		Demands to cope with stress predominate	GCs

Source: Modified from "The Concepts of Stress and Stress System Disorders: Overview of Physical and Behavioral Homeostasis," by G. P. Chrousos and P. W. Gold, 1992, *Journal of the American Medical Association*, 267(9), pp. 1244–1252.

physical consequences (Sapolsky et al., 2000). The repercussion of prolonged CRH and GC activity may be especially costly during development. High CRH levels, with or without elevated GCs, inhibit physical and neural development (Avishai-Eliner, Brunson, Sandman, & Baram, 2002). CRH and GCs also shape brain systems involved in perception and response to threat and, in genetically vulnerable individuals, may facilitate the development of psychopathology (Heim et al., 1997).

LHPA studies in humans are still largely confined to measures of cortisol and, more recently, the *anticortisol*, dehydroepiandrosterone (DHEA). Cortisol is a glucocorticoid that has catabolic effects; DHEA is an androgenic steroid that has anabolic effects. Both are produced by the adrenal cortex. Because measurements in humans are focused on these adrenocortical hormones, this has led to the misleading view that the pituitary-adrenal axis is at the center of the stress response. However, animal models and advanced molecular techniques make it clear that CRH and its system of receptors are as central as GCs (cortisol and corticosterone) for stress and adaptation. This can be demonstrated through description of stress-activating and regulatory pathways.

The Hypothalamic-Pituitary-Adrenocortical Axis

The circuits that originate in specific brain areas and activate the LHPA system converge, directly or indirectly, on the medial parvocellular region of the paraventricular nucleus (mpPVN) of the hypothalamus that secretes CRH

and arginine vasopressin (AVP; see Figure 13.1). Inputs to the mpPVN include both *activating* and *inhibiting pathways*. These pathways are similar in the rat and human (reviewed in Lopez, Akil, & Watson, 1999). Once released, both CRH and AVP interact with their receptors on corticotrophic cells of the anterior pituitary (AP), where the proopiomelanocortin (POMC) molecule is synthesized and processed into adrenocorticotrophic hormone (ACTH). Binding of CRH to pituitary CRH receptor 1 (CRH r1) leads to the secretion of ACTH. AVP potentiates CRH-induced ACTH release. ACTH circulates in blood and binds to its own receptors on the adrenal cortex, leading to the synthesis and release of GCs.

Mineralocorticoid and Glucocorticoid Receptors

GCs target many organs and tissues, including the brain. They have their effects through two types of receptors: mineralocorticoid (MR) and glucocorticoid (GR). Receptor binding, particularly to GR, also accomplishes negative feedback whereby GCs inhibit their own production. There are three types of negative feedback: fast, intermediate, and delayed. Fast feedback is rapid (within minutes) and dependent on the rate rather than the absolute magnitude of GC increase. It is achieved, at least in part, through GC binding to receptors in the mpPVN, AP, and hippocampus (reviewed in Dallman et al., 1992). Intermediate and delayed feedback, on the other hand, work over the course of hours to days to suppress CRH and POMC gene expression in the hypothalamus and AP, respectively, thereby decreasing the ACTH secretory drive. Thus, multiple feedback

Figure 13.1 The LHPA System. Panel A depicts the anatomy of the LHPA system and structures important in its regulation. AMY = Amygdala, HC = Hippocampus, HYP = Hypothalamus, NTS = Nucleus of the tractus solitarius, PFCtx = Prefrontal cortex. Panel B depicts the activation (+) and negative feedback inhibition (–) pathways of the HPA system. Increases in GCs are initiated by the release of CRH/AVP from the medial parvocellular region of the paraventricular nucleus (mpPVN) in the hypothalamus. Negative feedback inhibition operates through GCs acting at the level of the pituitary, hypothalamus and hippocampus. ACTH = Adrenocorticotrophic hormone, AVP = Arginine vasopressin, CRH = Corticotropin releasing hormone, GABA = Gamma aminobutyric acid.

loops operate in different time domains and through different processes (neuronal signaling as well as gene regulation) to maintain GCs within normal basal levels.

The effects of GCs depend on which receptor is bound (MR or GR), the ratio of MR to GR binding, and the recep-

tor's location (de Kloet, 1991). In the rodent brain, MRs are expressed in limbic regions (e.g., septum, hippocampus) and GRs are distributed throughout the brain. However, unlike rodents, humans express MR in cortical regions, suggesting an MR role in processive functions

related to stress (see later discussion, and reviewed in Lopez et al., 1999). MRs bind GCs readily (high affinity), and GRs bind GCs less readily (lower affinity); therefore, GCs bind first to MRs and then to GRs as MR sites saturate. MRs are typically about 80% to 90% bound or occupied when GCs are in basal ranges, with GRs being bound only at the peak of the circadian cycle or when stressors stimulate elevations over basal concentrations.

In addition to mediating negative feedback, in the brain both MRs and GRs mediate all GC effects. Outside the brain, MRs regulate water/salt balance through binding by aldosterone, another steroid hormone. In the periphery, GCs do not occupy MRs because of the presence of the enzyme 11 beta hydroxysteroid dehydrogenase (11 β -HSD) that inactivates GCs. In the brain, 11 β -HSD is minimally expressed so that MR exhibits its high affinity for GCs (Reul & de Kloet, 1985). Through brain MRs and GRs, GCs serve at least four critical stress functions (reviewed in Sapolsky et al., 2000). MRs mediate *permissive* GC effects that sustain an organism's ability to make adaptive responses to changing environmental demands. For example, MRs maintain steady and persistent electrical current, allowing neurons to be responsive to their neurotransmitters. In contrast, GRs have *suppressive* effects, inhibiting ongoing behavioral and neurophysiological responses. *MR and GR, thus, tend to have opposing effects.* Several additional examples of these opposing effects help demonstrate this general rule. MRs facilitate cerebral glucose utilization, and GRs inhibit glucose utilization throughout the brain. MRs mediate forms of synaptic plasticity that underlie learning; GRs, operating over hours or days, disrupt the same mechanisms of synaptic plasticity, endanger cell survival, and blunt hippocampal excitability, disrupting memory formation. The opposing effects of MR and GR combined with the differential affinity of GCs for these two receptors is believed to be why the relations between GCs and adaptive functioning often takes an inverted-U function. Thus, very low and very high GC concentrations are associated with deleterious health and behavior consequences, and moderate levels and small or well-constrained elevations tend to support adaptive functioning.

In addition to levels and duration, the timing of the GC response also influences its role in stress and adaptation. Initial effects of increasing levels of GCs tend to be *stimulatory* and permissive as these operate through MR and initial GR effects of liberating hepatic energy stores, resulting in increased glucose levels and permissive GR effects on other stress-stimulated physiological systems. Well-timed anticipatory responses to stressors thus can

place the organism in an optimal state to handle challenge and constrain or suppress the operation of other stress-sensitive systems. Therefore, not only too persistent but also too shallow GC responses above resting basal levels can be damaging, particularly when this permits other stress-stimulated physiological responses to continue unchecked (e.g., immune reactions). The final category of GC effects is *preparatory*, denoting GC-induced changes in neurobiology that affect the way organisms responds to subsequent stressors. Thus, for example, operating through GRs, GCs up-regulate the sensitivity of the amygdala to threat stimuli, resulting in heightened sensitivity to subsequent threats (for review, see Rosen & Schulkin, 1998).

The effects of GCs depend not only on their level and timing, but also on the ratio of MRs to GRs that are occupied in different brain regions (de Kloet, 1991). This is demonstrated using transgenic preparations (reviewed in Korte, 2001). Transgenic mice that underexpress GR produce high and prolonged GC responses (impaired feedback), are hyperactive, and have great difficulty with spatial learning, presumably because of secondary hippocampal effects. Transgenic mice that overexpress GR have increased anxiety-related behavior with increased CRH expression in the amygdala, unaltered CRH levels in the PVN, and normal basal GC levels. MR knock-outs have impaired neurogenesis presumably secondary to chronic elevations in basal GC levels.

Systemic versus Processive Stress and Their Neuroanatomical Pathways

A number of seemingly disparate stimuli activate the LHPA axis. Some stimuli activate the axis through *systemic* paths; others require interpretation by the organism and thus are termed *processive or collative* (reviewed in Herman & Cullinan, 1997). Systemic stressors are physical and context-independent. Thus, they stimulate the LHPA axis even in an unconscious animal. Examples are hypotension (decreases in blood pressure), hypoxia (decreases in oxygen levels), and infection. In contrast, processive stressors are context-dependent, requiring the comparison of current information with past experience and the assignment of *emotional meaning*. Systemic and processive stressors operate through diffuse networks of neurons that converge at the level of the mpPVN. For systemic stressors, the information stimulating activation of the LHPA is relayed to the mpPVN via the brain stem through afferents originating in the dorsal roots of the autonomic system and the glossopharyngeal and vagus cranial nerves. For example, the nucleus

of the tractus solitarius (NTS, a key parasympathetic relay station) receives afferent fibers that indicate hypotension as a result of hemorrhage. In turn, *efferent fibers travel away* from NTS into the CRH-rich mpPVN area to activate an LHPA response. Some of these autonomic connections are direct into the mpPVN, but most are indirect via other limbic structures.

Limbic centers transmit processive stressor information to the mpPVN via corticolimbic *efferent* pathways involving the BNST (bed nucleus of the stria terminalis), preoptic nucleus, lateral and medial septum, the amygdala, prefrontal cortex, and ventral subiculum (reviewed in Herman et al., 2003). Efferent pathways converge in the fimbria/fornix, a collection of nerve bundles emanating from the hippocampus, subiculum, and cortical regions. Some of these pathways provide activating and others inhibiting input to the mpPVN. The medial amygdala and lateral BNST are centrally involved in *activating pathways*. The various nuclei of the amygdala mediate behavioral and also autonomic cardiovascular responses to stress indirectly using the BNST or NTS as relay stations, with the fibers terminating two or more steps removed from the mpPVN (de Olmos, Alheid, & Beltramino, 1985). Whether or not cardiovascular effects are induced along with LHPA activation depends on the nuclei excited by stress-induced amygdala activation (e.g., basolateral versus basomedial; M. Davis, 1992).

For processive stressors, *inhibitory influences* are also mediated through limbic structures: the ventral subiculum, preoptic area, medial BNST, and cingulate/prefrontal cortex (Herman, Muller, & Figueiredo, 2004). Damage to the subiculum, its major outflow pathway (the fimbria/fornix), or the medial frontal cortex increases CRH mpPVN expression and enhances GC production to processive stressors. However, some overlap in excitatory and inhibitory inputs exists as medial prefrontal cortex damage has been shown to both increase and decrease GC production and autonomic activation (reviewed in Herman et al., 2003; C. D. Walker, Welberg, & Plotsky, 2002).

Neurotransmitters and the Limbic-Hypothalamic-Pituitary-Adrenocortical Axis

Neurotransmitters are the mediators of LHPA activity that operate along the neuroanatomical pathways outlined earlier (see Figure 13.2). Many neurotransmitter systems exist in the brain, but noradrenaline (NA), serotonin (5-HT), glutamate, and gamma-aminobutyric-acid (GABA) are particularly important in modulation of the LHPA system. All of these molecules have excitatory effects on the LHPA

axis through their innervation of limbic structures that, in turn, have direct access to the mpPVN (reviewed in Herman et al., 2003). This excitatory stimulation operates through ascending monoaminergic input from the pons area, where presynaptic neurons containing NA (locus coeruleus) and 5-HT (raphe nuclei) originate. Direct activation of the LHPA system, however, involves short circuits arising from glutamate neurons within the mpPVN that act on glutaminergic receptors (NMDA, kainate, or AMPA) and through inhibition of inhibitory GABA-ergic afferents (because double negative equals positive; see later discussion and Figure 13.2).

Inhibition of the LHPA axis at the level of the mpPVN is mediated through GABA-ergic neurons. The inhibitory structures (e.g., septum, prefrontal cortex, medial BNST, and suprachiasmatic nucleus) are rich in GABA neurons (Herman et al., 2004). GABA modulation is how GRs in the hippocampus mediate negative feedback. GR-activated electrical currents travel through hippocampal efferents to interact with GABA-containing neurons in the BNST, preoptic area, and hypothalamus, achieving a net inhibition on the mpPVN. Activation of the LHPA system also can involve GABA activity. In this case, GABA interacts with adjacent GABA neurons and results in a decrease of the downstream inhibition (first GABA neuron inhibits the release of a second GABA neuron). Amygdala innervation of the mpPVN is a good example of this double negative. Enhanced amygdaloid activity leads to disinhibition of disynaptic GABA-ergic input to the mpPVN and therefore enhances LHPA activity (see Figure 13.2). GABA-ergic tone is also the main factor influencing resting basal state of the LHPA axis, characterized by circadian oscillations of its key hormones (see later discussion).

Critical Features of Processive Stressors in Humans

Although the neuroanatomical pathways of processive stressors are beginning to be worked out in studies of animals, in human research the key features of processive stimuli capable of activating an LHPA response are still uncertain. These features have variously been described as novelty, uncertainty, unpredictability, uncontrollability, and potential for harm or loss (see reviews by Kirschbaum & Hellhammer, 1989, 1994). Distressingly, however, despite arguments that the LHPA axis is highly sensitive to processive stressors, it is often difficult to provoke GC responses in the laboratory (see review by Biondi & Picardi, 1999). Indeed, in many laboratory studies of children and adolescents, rather than an increase in cortisol to the

* Glucocorticoids provide positive stimulation to the amygdala for the synthesis and release of CRH, but negative to the pituitary, hypothalamus and hippocampus.

† Interaction is through glutamate outflow from these regions that synapse on local GABAergic neurons, producing inhibition of mpPVN.

Figure 13.2 Schematic representation of the activating (right side) and inhibiting (left side) circuits that contribute to regulation of the LHPA system. Catecholamines, *norepinephrine* (NE) and *epinephrine* (E) arising from medullary nuclei of the brainstem are the primary neurotransmitters providing activation of CRH synthesis and release from the mpPVN. *Serotonin* originating from dorsal raphe is weakly activating; it act both directly on mpPVN and indirectly through *excitatory glutamate neurons* or *inhibitory gamma aminobutyric acid (GABA)* inputs. Paradoxically, the inhibitory GABA neurotransmitter activates the mpPVN to secrete CRH since two GABA neurons activated in series leads to excitation and not inhibition. *Extra-hypothalamic CRH* also acts as a neurotransmitter to initiate autonomic and behavioral responses to stress. The activation of the extra-hypothalamic CRH system is initiated by rising glucocorticoids levels that operate on the amygdala to secrete CRH that, in turn, impacts on the locus coeruleus (LC). Through the activation of catecholaminergic brainstem nuclei there is also stimulation of descending pathways leading to NE/E release from the adrenal medulla that facilitates cardiovascular autonomic responses to stress. Inhibition of the LHPA axis seen in the left side is provided by *glucocorticoids* acting on glucocorticoids receptors (GR) in the hypothalamus and pituitary where CRH and ACTH release is halted. The hippocampus serves to inhibit the stress response via multiple circuits, some of which are direct inhibitory GABA inputs; others are indirect through glutamate excitatory inputs to GABA neurons converging in the mpPVN. GABA neurons located in each of the structures further modify the stress reactivity and inhibition from other brain regions such as the thalamus, association cortex, cortical and limbic afferents.

intended stressor, cortisol levels for most subjects fall over the testing period! This may reflect anticipatory increases in GCs and inadequate periods for adaptation to the laboratory, but it may also reflect our lack of understanding of the stimuli capable of activating the LHPA axis in humans.

In a recent meta-analytic review of 208 adult studies, Dickerson and Kemeny (2004) provide an empirical test of the core features of potent GC-stimulating tasks. They argued that for an event to activate the LHPA system, goals that are central to the individual must be threatened. Self-preservation is a central goal of all living organisms. Certainly, physical threats to self-preservation are likely to produce marked increases in cortisol, as evidenced by studies of individuals in emergency rooms assessed shortly after life-threatening events (see Yehuda, 2000). These authors argue, however, that the preservation of the *social self* is also a central goal for humans. The results of their meta-analysis showed that paradigms that threaten the social self (e.g., social evaluation by an audience of judges) are potent stimulators of the LHPA axis. Tasks that require mental effort but where poor performance poses little threat to the social self are not very effective in elevating cortisol. Tasks that produce negative emotions but do not threaten the social self are not effective in elevating GCs. Novelty, unpredictability, and uncontrollability act synergistically with threats to central goals to produce the most marked GC responses.

No one has conducted a similar meta-analysis of stressors in children. However, in early childhood, separation activates the LHPA axis, an event that has an evolutionary history of threatening self-preservation. Later in childhood, Flinn and England (1995) have reported, serious family conflicts and threats of rejection/abandonment are highly potent in elevating cortisol in their study of Caribbean children. In addition, even very early in life, social rejection by peers is associated with high GC levels among preschool children (Gunnar, Tout, Donzella, & van Dulmen, 2003). Thus, it seems likely that the Dickerson and Kemeny (2004) analysis will apply to children. Critically, because it is rare to find a laboratory study beyond the infancy period in which the stressor elevates cortisol in most children, it is challenging to interpret the result of most laboratory-based, GC human developmental stress studies.

A System with a Rhythm

The LHPA axis is not just an alarm system waiting to be activated. It is also a system that exhibits a *circadian* or 24-hour rhythm. GC levels reach their peak approximately 30 minutes after waking, although they begin to rise in the last hours of sleep. From peak levels, GCs fall throughout the day, with transient increases about 45 minutes following

protein-rich meals (postprandial surge), until levels reach their lowest point or nadir at the end of the activity phase (e.g., Kwak, Morano, Young, Watson, & Akil, 1993). GCs measured in saliva follow the same pattern, offset by approximately 2 minutes, from GCs measured in plasma. The circadian rhythm not only alters basal levels of the hormones along the LHPA axis, but also changes in its sensitivity to stressful stimuli. At the nadir of the rhythm (roughly 10 to 12 p.m. in humans on a regular day/night schedule), the LHPA system is more responsive to both activating and inhibiting (negative feedback) signals (Dallman et al., 1992). Thus, time of day is a critical factor in interpreting LHPA effects and designing LHPA studies.

The need to control for diurnal rhythm in assessing activity of the LHPA system places critical restrictions on researchers studying this system. However, in human developmental research, time of day often is not controlled. It is not clear how much of a problem this poses. In their review, Dickerson and Kemeny (2004) were not able to detect differences in the magnitude of the adult GC response depending on whether assessments were made in the morning or afternoon. Although this would seem to stand in marked contrast to the animal studies, the human studies deal with a smaller time of day variation. Rather than contrasting LHPA activity at the peak and nadir of the cycle (wake-up and bedtime), testing times in human studies typically vary across the mid-portion of the day. This is especially true for studies with children, for whom testing schedules are constrained by such factors as when the child typically naps and when other family members get home from work or school. It may be that when testing occurs between 9 a.m. and 5 p.m., variations in testing times introduce little variability in the responsiveness of the system. On the other hand, until the appropriate meta-analysis of the child development literature on cortisol reactivity is conducted, it is probably better to avoid testing times that vary uncontrollably between subjects.

The LHPA circadian rhythm is one of many physiological (e.g., body temperature) and behavioral (e.g., sleep, feeding) rhythms in mammals. The suprachiasmatic nucleus (SCN) is the master pacemaker controlling circadian rhythms (reviewed in van Esseveldt, Lehman, & Boer, 2000). It oscillates with a near 24-hour period under constant light conditions but is entrained to day/night rhythm by periodicity of light exposure and nonphotic modulators, including patterns of locomotor activity, feeding and sleep (Follenius, Brandenberger, Bandesapt, Libert, & Ehrhart, 1992; Follenius, Brandenberger, Hietter, Simeoni, & Reinhardt, 1982). In humans, the SCN is also entrained by our expectations about when we are to wake up in the morning (Born, Hansen, Marshall, Mollé, & Fehm, 1999). For example, if we expect

to wake up at 6 A.M., activity of the LHPA system will reflect that expectation, regardless of when we actually wake up. Thus, not only the time since waking but also whether the individual is waking at his or her usual time is important to consider in assessing early morning cortisol concentrations. Unfortunately, we do not know what happens to the circadian rhythm when bedtimes and wake-up times are unpredictable, as they may be in more chaotic households. Sleep restriction also modifies LHPA axis activity, leading to elevated resting GC levels (Leproult, Copinschi, Buxton, & Van Cauter, 1997). Thus, sleep-wake rhythms are important to consider in studies of LHPA activity.

The pathways that integrate the perception of light into the SCN are the retinohypothalamic tract (GABA-ergic), the geniculohypothalamic tract (neuropeptide Y or NPY), and raphe (5-HT). The nonphotic input is received from the cortex, basal forebrain, and hypothalamus using NPY, 5-HT, and possibly GCs (Liu & Reppert, 2000). A myriad of neuropeptides are expressed in the SCN; however, it is likely that the GABA-ergic system plays a more important role than these neuropeptides in transmitting the rhythmic function of the SCN to other brain regions (Liu & Reppert, 2000). Once a circadian rhythm is generated in the SCN, it is imposed on the mpPVN primarily via projections into the brain stem autonomic centers (Herman et al., 2003). But there is also an ACTH independent multisynaptic projection to the adrenal that results in a fast decrease of circulating GCs at the beginning of sleep (Buijs et al., 1999). This pathway helps explain why activation of the axis at the nadir of the LHPA rhythm around the onset of nighttime sleep in humans results in greater GC responses than activation at the peak of the circadian rhythm (Kaneko, Hiroshige, Shinsako, & Dallman, 1980).

In the LHPA system, MRs play a critical role in maintaining the LHPA basal rhythm. This relationship has been demonstrated by using antagonists that are specific to MR or GR (reviewed in de Kloet, 1991). Selective MR antagonists produce *elevated* basal GCs near the nadir of the rhythm without affecting levels near the circadian peak or responses to a processive stressor. Conversely, selective GR antagonists have *no effect on resting basal* or restraint stress GC levels at any time of day. Combining MR and GR antagonists, however, produces elevated GCs over the entire day as well as increased elevations to stressors. In humans, pharmacological MR antagonists also increase cortisol levels in the evening, near the nadir of the LHPA rhythm (e.g., Grottoli et al., 2002; but see Michelson, Chrousos, & Gold, 1994). In sum, MR activation is necessary and sufficient to maintain low basal GC levels during

the nadir of the circadian rhythm, whereas MR and GR activation is necessary to constrain GC secretion during the circadian peak and during acute stress.

The circadian rhythm of cortisol can be observed in humans as early as 6 to 12 weeks of life (Larson, White, Cochran, Donzella, & Gunnar, 1998). However, throughout infancy and early childhood, cortisol production from mid-morning through late afternoon fluctuates markedly with naps and feedings (for review, see Gunnar & Donzella, 2002). As children give up their daytime naps, the typical adult diurnal pattern of cortisol production emerges (Wata-mura, Donzella, Kertes, & Gunnar, 2004). Ambulatory studies of salivary cortisol have shown that not all individuals reliably produce this diurnal pattern of cortisol production. Even in the absence of frank physical or mental disorders, about 10% to 15% of the adult population appears to have days when early morning levels are not high and/or evening levels are not low (Smyth et al., 1997). The etiology and significance of these atypical patterns is not well understood (see Heim, Ehlert, & Hellhammer, 2000), although they have been associated with emotional and mental exhaustion (e.g., burnout), chronic pain disorders (e.g., fibromyalgia), and, in infants and young children, conditions of chronic neglect (Gunnar & Vazquez, 2001).

In addition to the classic diurnal pattern, recently it has been noted that there is about a 60% increase in salivary cortisol concentration in the 30 to 40 minutes after waking. Termed the *cortisol awakening response* (CAR), this increase is stable within individuals and reflects genetic as well as other factors (Wüst, Federenko, Hellhammer, & Kirschbaum, 2000). Individuals with constant work overload and chronic worries tend to exhibit larger increases in cortisol upon waking (Schlotz, Hellhammer, Schultz, & Stone, 2004).

Stability and Heritability

Studies of the LHPA axis often focus on individual differences, thus making it essential that we understand the reliability of these differences. Regarding *basal cortisol*, using latent state-trait modeling it has been shown that the balance of state and trait components varies over the day, with generally larger trait components obtained soon after morning awakening and larger state components obtained later in the day (Kirschbaum et al., 1990; Shirtcliff, Granger, Booth, & Johnson, in press). In fact, it has been difficult to fit state-trait models to cortisol measures obtained later in the day because state variability is so large that stable trait components are difficult to discern (e.g., Kirschbaum et al., 1990). Assessing the stability of the LHPA *stress* response is more complicated because the

same stressor repeated a second time is not as novel and thus would be expected to produce less activation. Furthermore, different stressors operate over different neural pathways and thus produce different responses. However, several researchers have recently reported modest test-retest stability (e.g., *rs* of around .5) in cortisol responses to stressors in infancy (e.g., Goldberg et al., 2003; Lewis & Ramsay, 1995). E. F. Walker, Walder, and Reynolds (2001) also noted rank-order stability of a similar magnitude in their study of adolescents assessed over a 2-year period. As in other psychometric measurement, aggregation tends to produce more reliable indices. For example, in one study using the Trier Social Stress Test (TSST) administered repeatedly over several days, the GC response to the first TSST did not correlate with responses to the later TSSTs, but GC responses to the later TSSTs were correlated (Pruessner et al., 1997). In addition, although the GC response to the first TSST was not correlated with personality traits, responses to the later TSSTs were, particularly when these responses were averaged. Unfortunately, there is little information on how many GC values need to be aggregated before reliable individual difference estimates are obtained. And, given the state-trait modeling results, the number needed likely varies with time of day. Another reliability-reducing factor may be individual differences in the rise time of the response. Ramsay and Lewis (2003) showed that when cortisol measures were taken repeatedly following an inoculation stressor in infants, the average peak response was at approximately 25 minutes poststimulation. However, there was a substantial number of infants who reached their peak cortisol levels at other time points. When only two measures (pre- and post-) are taken, it is very possible that delta cortisol underestimates cortisol reactivity for many individuals.

Stable individual differences in LHPA activity may partly reflect genetic influences. A recent review of human twin studies concluded that these influences were only modest (Bartels, van den Berg, Sluyter, Boomsma, & de Geus, 2003). However, in most of the reviewed studies, only a single, potentially unreliable, cortisol measure was obtained. To address the problem of limited measurement, these authors analyzed salivary cortisol data collected at four points over the day on 2 school days in 209 12-year-old twin pairs. Heritability estimates varied over the daytime cycle. They were weak ($h^2 = .32$) at the moment of waking, highest 30 to 40 minutes postwaking ($h^2 = .71$), modest late in the morning ($h^2 = .43$), and absent or undetectable in the evening before bed. These data fit with the latent state-trait modeling results, suggesting that cortisol levels 30 to 40 minutes after morning awakening exhibit a heritable trait

component, whereas those taken at other points in the day reflect stronger, unique, and possibly transient environmental or internal state effects. Basal levels later in the day are likely to exhibit heritable influences, but it may take many more than 2 days of cortisol assessment to obtain measures that are reliable enough to yield significant heritability estimates.

THE DEVELOPING LIMBIC-HYPOTHALAMIC-PITUITARY-ADRENOCORTICAL SYSTEM

The rules governing activity of the LHPA axis in adults differ from those for the neonate. Most of this evidence comes from studies of rats. We describe preclinical or animal research and then consider how this information applies to human development. In rats, during the first 2 postnatal weeks (postnatal days 4 to 14), ACTH and GC responses to many stressors are markedly diminished. This period has been termed the relative stress-hyporesponsive period (SHRP). Although GC responses are low during the SHRP, marked stressor responses can be observed in the hypothalamus and other brain regions in a species- and developmentally specific manner (Smith, Kim, Van Oers, & Levine, 1997; C. D. Walker, Scribner, Cascio, & Dallman, 1991). Structural and functional brain immaturity and marked developmental changes in the adrenal gland appear to underlie these developmental differences.

Key Features of the Developing Limbic-Hypothalamic-Pituitary-Adrenocortical System

The LHPA system undergoes marked changes during development. Here we briefly review the changes most pertinent to our understanding of developmental psychopathology in relation to LHPA functioning.

The Adrenal and Glucocortical Secretion

In the mature animal, the adrenal glands consist of two divisions: a cortex that produces three types of steroids and a medulla that produces catecholamines. The three steroids produced by the cortex are derived from morphologically and functionally distinct zones (Parker & Schimmer, 2001). The zona glomerulosa (ZG) synthesizes GCs; the zona fasciculata (ZF) produces mineralocorticoids (MCs), and the zona reticulata (ZR) produces sex steroids. Prenatally, the maternal placenta and the fetal adrenal cortex constitute a fetal-placental unit. The fetal adrenal cortex consists primarily of one zone (fetal zone), which

is equivalent to the reticulata and is geared to the production of estrogen precursors. These molecules are transferred from the fetus to the placenta, where they are metabolized to estrogen, essential for the maintenance of pregnancy. As gestation progresses, a primitive ZG develops and begins producing GCs. At birth, GC levels are elevated as a consequence of the stress of parturition. In the rat, due to hepatic immaturity, it takes a long time for the pup to clear GCs from circulation. However, by postnatal day (PND) 4, basal GC levels are low in the rat pup and remain low through PND 14, the period of the SHRP (C. D. Walker et al., 1991). Parturition also initiates an ischemic process resulting in involution (developmental removal) of the fetal zone.

For ACTH to stimulate GC production, cell-specific gene expression leading to specific enzyme synthesis is required in the ZG. However, the development of chromaffin cells in the adrenal medulla also plays a role (reviewed in Vazquez & Levine, in press). Isolated adrenal cells lose the capacity to produce GCs unless chromaffin cells from the medulla are added to cell culture preparations. In the rat, the adrenal medulla does not become a well-defined region until the end of the first postnatal week, corresponding to a period of rapid development of the GC- and MC-producing zones of the adrenal cortex. Thus, the adrenal is quite immature in the rat during the first 2 weeks postnatal, a fact consistent with the SHRP.

Yet, there are environmental events that can stimulate marked GC responses in the neonatal rat. Among these is removal of the mother for 24 hours. Maternal absence for this duration raises GC levels and permits the adrenal to respond to both stressors and ACTH (see Vazquez & Levine, in press). Feeding (milk into the gut) and stroking help to block this effect, suggesting that it may be partially mediated by feedback through autonomically mediated pathways from the gut and skin. Recent studies suggest that the nutritive components in milk can also modulate the response of the neuroendocrine system to stress and, possibly, influence some aspects of brain development (see review, C. D. Walker et al., 2004). In particular, fat and leptin, a protein produced in the adipose tissue and present in maternal milk in both humans and rodents, reduces responses to stress in the infant. This is different in the adult, in which high-fat feedings exacerbates the LHPA response to stress. Although the mechanisms involved in this phenomenon are not clear, Walker and colleagues suggest that leptin acts on both central (hypothalamus and hippocampus) and peripheral (pituitary, adrenal gland) systems in the infant to reduce exposure to GCs and enhance hippocampal development during a sensitive period of brain development. Table 13.2

lists genes that are modulated by endogenous and synthetic GCs in developing mammals.

The Anterior Pituitary

Consistent with the immaturity of the adrenal and the relevance of the adrenal fetal zone during gestation, the anterior pituitary (AP) also displays marked morphological and functional changes during fetal and early postnatal development in the rat pup. The development of the AP from epidermal precursor cells is under the control of transcription factors that are expressed early in embryogenesis (reviewed in Swanson, 1992). Hypothalamic hormones help differentiate specific AP cells that produce specific hormones. In the late fetal/early postnatal period, the AP contains more ACTH-producing cells (corticotrophs) than in the mature rat. Corticotrophs are among the first AP cells to mature, being functional by gestational day 16. However, the ability to process POMC into mature ACTH develops only gradually (for review, see Vazquez, 1998; C. D. Walker et al., 2002). During gestation, high molecular ACTH forms predominate that may be important for fostering development of the adrenal and for maintaining the fetal-placental unit but stimulate minimal GC production. During the late fetal and early postnatal period, the ACTH molecules produced by corticotroph cells gradually change to increasingly yield GC-stimulating forms. Corticotroph cells express receptors for CRH (i.e., CRHr1) by late gestation, with numbers declining from PND 5 to adulthood. AVP receptors follow a similar developmental pattern but are not functionally coupled to second messenger systems until PND 10. Thus, consistent with the waning of the SHRP, after PND 10, the AP exhibits increasing capacity to produce mature ACTH and mature responses to both CRH and AVP by the end of the 2nd week.

Hypothalamic Corticotropin-Releasing Hormone

In the rat, by gestational day (GD) 17, neurosecretory neurons appear in the mpPVN along with evidence of CRH mRNA. One day later, AVP mRNA can be observed. Soon after, CRH and AVP levels begin to increase. At approximately this same time, axon terminals containing granular vesicles can be seen in the external layer of the median eminence. However, the mpPVN is not completely mature until PND 28, the time of typical weaning in the wild (Bugnon, Fellmann, Gouget, & Cardot, 1982). CRH receptors herald the emergence of a functional role for CRH in the brain and pituitary. The distribution of these CRH receptors (1 and 2) is very similar in both the developing and mature rodent. However, several brain regions have high expression of both CRHr1 and r2 early in life, followed by a

TABLE 13.2 Partial Listing of Genes Modulated by Endogenous and Synthetic Glucocorticoids in the Developing Mammal*Brain Cell Lineages and Differentiation*

Bax induces apoptosis. Low GCs increase bax mRNA levels in adult rats (Cardenas et al., 2002).

Bcl-2 prevents apoptosis and neutralizes effects of bax. Low GCs increase bcl-2 mRNA levels (Cardenas et al., 2002).

Ay controls epidermal cell lineage migration. GCs decrease birthweights and increase rates of cleft palate, as examined using prenatal rats (E18; Teramoto, Hatakenaka, & Shirasu, 1991).

Myelin basic protein functions in the development of myelin. GCs increase mRNA levels of this gene in oligodendrocytes, as detected in the neonatal rat (Kumar, Cole, Chiappelli, & de Vellis, 1989).

GPDH plays a role in oligodendrocyte differentiation and myelinogenesis. GCs increase its tRNA levels in oligodendrocyte nuclei (Kumar et al., 1989).

GFAP is an astrocytic marker. In postnatal (2 wks) rats, GCs increase GFAP expression (O'Callaghan, Brinton, & McEwen, 1991).

NGF is required for the development of sympathetic neurons and some sensory neurons. In postnatal (PND11) rats, GCs increase prefrontal cortex (both sexes) and hippocampal (males) NGF; low GCs cause changes in distribution and expression of NGF receptors in the hippocampus (Scacianoce, Catalani, Lombardo, Consoli, & Angelucci, 2001).

Glutamine synthetase catalyzes recycling of glutamine in glial cells. In embryonic rats, inhibition of GC receptors suppresses the expression of this gene (Vardimon, Ben-Dror, Avisar, Oren, & Shiftan, 1999).

Glucocorticoid receptor plays a critical role in regulation of the HPA axis. In sheep and rats late in gestation, GCs increase GR mRNA levels (Holloway, Whittle, & Challis, 2001).

Anterior Pituitary

POMC is the pro-hormone that is cleaved to yield ACTH. GCs reduce POMC mRNA levels, as noted in late-gestation sheep (Holloway et al., 2001).

Vasopressin receptor (V1b) regulates AP response to vasopressin. GCs decrease V1b receptor expression in the AP, as shown in sheep (E100; Young, Smith, Figueroa, & Rose, 2003).

Prolactin is critical in lactation and delivery. GCs in sheep (E130-E140) increase prolactin mRNA in the AP (Phillips, Fielke, Young, & McMillen, 1996).

FTB controls maturation of glycoprotein galactosylation and fucosylation processes important for hormonal bioactivity. In neonatal rats, GCs increase its transcriptional regulation (Biol-N'gargba, Niepceon, Mathian, & Louisot, 2003).

Peripheral Catecholaminergic System

PNMT is the rate-limiting enzyme in adrenaline synthesis. GCs regulate PNMT activity throughout life, and GR appears to be necessary for the developmental appearance of PNMT expression (Anderson & Michelsohn, 1989).

PENK gene regulates enkephaline-related peptide in chromaffin cells. GCs reduce adrenal PENK mRNA levels, as shown in fetal sheep (E124; Fraser, Matthews, Braems, Jeffray, & Challis, 1997).

Inflammation

HLA-G plays a critical role in inflammation. In cells cultured from humans (E7-9), GCs enhance transcription of HLA-G in trophoblasts (Moreau et al., 2001).

Proteolipid protein may trigger the immune system to attack myelin. GCs increase mRNA levels in oligodendrocytes, as shown in neonatal rat brain tissue (Kumar et al., 1989).

Physical Growth

IGF-II regulates cell proliferation and metabolism. Low GCs increase hepatic transcription rate of IGF-II, as shown in late-gestation sheep gene culture (Kumar et al., 1989).

CTGF/IGFBP rP2 plays a role in bone formation. In E22 rats, GCs cause a time- and dose-dependent increase in mRNA levels in bone cells and increase transcription rate (Pereira, Durant, & Canalis, 2000).

GHR-1A, GHR-2, and GHR-3 regulate this family of growth hormone receptors, which directly stimulate the production of IGF-1 in the liver and other tissues. As shown in fetal sheep, increases in GCs during fetal development stimulate increases in GRH mRNA (Li, Gilmour, Saunders, Dauncey, & Fowden, 1999).

IGF binding protein-1 regulates IGF availability in postnatal life and contributes to somatic growth in utero. In fetal rat livers, GCs increase synthesis of IGFBP-1 (Menuelle, Babajko, & Plas, 1999).

Tryptophan oxygenase is an enzyme required for normal growth and development. In neonatal rat livers, GCs increase tryptophan oxygenase mRNA (Nagao, Nakamura, & Ichihara, 1986).

Alpha 1 (I) procollagen plays a role in proper osteoblast proliferation. In rats (calvaria cultures), GCs decrease alpha I (I) procollagen transcripts (Delany, Gabbitas, & Canalis, 1995).

Respiratory System

TTF-1 regulates thyroid transcription factor-1, which plays a role in lung morphogenesis and is involved in the transcription of surfactant proteins. Synthetic GCs increase mRNA expression of TTF-1 in rats with congenital hypoplasia.

LGL2 is coordinated with key transcription factors that regulate signal transduction pathways in the fetal lung. In rats (E14) and humans (gestational week 16), GCs induce LGL2 (Zhang et al., 2000).

SP-A, SP-B, and SP-C (surfactant proteins) are critical for respiration. Three variants of these proteins (A, B, and C) work in coordination to reduce alveolar surface tension at the air-liquid interface in lung tissue. In humans, GCs induce surfactant proteins (Losada, Tovar, Xia, Diez-Pardo, & Santisteban, 2000). In rats with congenital hypoplasia, synthetic GCs increase SP-B mRNA levels (Losada et al., 2000). In human lung tissue, synthetic GCs in coordination with DBcAMP reduce SP-A mRNA levels (McCormick & Mendelson, 1994; though see contradictory results in rabbit fetal lung tissue, Durham, Wohlford-Lenane, & Snyder, 1993). In fetal rabbit lung tissue, synthetic GCs, as well as GCs increased due to maternal stress, increase SP-C mRNA levels (Durham et al., 1993).

decline. For example, in the pyramidal region of the hippocampus and frontal cortex, CRHr1 are two- to fourfold higher during the 1st week of life and then decline to adult levels by postnatal day 12 (Avishai-Eliner, Yi, & Baram, 1996). CRHr2 are detected in the frontal cortex only during fetal and early postnatal life (Eghbal-Ahmadi et al., 1998). These distinct developmental profiles indicate a precise regulation of these receptors during development and the possibility that alteration of these profiles in areas critical to physiological and behavioral responses to stressors may be targets of early experience effects.

Monoamines

During the postnatal period in the rat, monoamine circuitry is being laid down and fine-tuned. The pattern of overproliferation and pruning of the major neurotransmitter systems in the rat (discussed in Vazquez et al., 1998) and human (summarized in Spinelli, 1987) have been described elsewhere. For example, in the rat, 5-HT-containing cell bodies are present at birth, reach maximum density by PND 14, and then decline to the adult innervation pattern by puberty (i.e., PND 35 to 45). The 5-HT receptor system follows a similar developmental course. Notably, development of the serotonin system corresponds to development of the LHPA stress response. Thus, increased levels of brain 5-HT metabolites following stress are observed around PND 12 in the rat pup, which is also when the LHPA response to stress becomes more predictable (Mitchell, Iny, & Meaney, 1990). GCs also influence the development of the 5-HT system, affecting the expression of the rate-limiting enzymes for 5-HT production (Singh, Corley, Phan, & Boadle-Bider, 1990). A similar developmental pattern is observed for the central NA system that again is linked closely to the ability of the NA system to activate the LHPA system (Herrenkohl, Ribary, Schlumpf, & Lichtensteiger, 1988). Here, too, GCs influence activity of the adrenergic system, in part through regulating levels of its rate-limiting enzymes (Markey, Towle, & Sze, 1982). Thus, there are bidirectional interactions between the ability to mount an LHPA response and the development of the brain monoaminergic systems.

Glucocorticoid Receptors

Both MR and GR receptors develop quite early in gestation in the rat and presumably also the human brain. Overall, MR density is greater during the early postnatal period than later in life in the rat (Vazquez et al., 1998; Vazquez, Morano, Lopez, Watson, & Akil, 1993). GRs are observed as early as GD 13 and are evident between GD 15 and 22 in the hippocampus, mpPVN, and locus

coeruleus. Different regions of the hippocampus display different developmental progressions. MR and GR are most abundant around PND 10 in the rat, with GR mRNA reaching adult levels after this time. In contrast, MR mRNA in the hippocampal dentate gyrus does not reach adult distributions until around PND 28 (for review, see Vazquez, Morano, et al., 1993). Overall, the hippocampal GR system matures long before the animal is capable of feedback inhibition. This likely reflects continued immaturity of connections of the hippocampus to the mpPVN (Vazquez & Akil, 1993). As noted earlier, emotional reactivity appears to be linked to hippocampal corticoid receptor expression, with an optimal balance of MR to GR argued to be critical to a number of functions (de Kloet, 1991). The MR and GR systems exhibit developmental changes and are highly sensitive to early experiences in the rat.

Circulating Glucocorticoids and Their Role in Development

Low GC levels in young organisms do not necessarily mean low levels of biologically active hormone. Most GCs in mature animals are bound to corticosteroid-binding globulin (CBG) and other proteins. Only the unbound or free GC can bind to receptors and thus have biological effects. In neonatal rats and humans, CBG and other binding globulins are low, and thus most circulating GCs have biological activity (Hadjian, Chedin, Cochet, & Chambaz, 1975; Henning, 1978). Furthermore, the clearance of GCs from the circulation is significantly slower in the pup and in the human newborn than in the adult. Thus, despite low plasma levels of GCs during the SHRP in rats and during the newborn period in humans, the levels of biologically active GCs are more than sufficient to have marked physiological effects.

GCs are steroid hormones, and as such, their receptors do not lie on the surface of cells (as is the case for neurotransmitters) but in the cytosol inside the cell (Lombroso & Sapolsky, 1998). In the cytosol of brain cells, GCs bind with either MR or GR to form GC-receptor complexes that then move into the cell nucleus and bind to the promoter regions of many different genes, initiating or inhibiting synthesis of different cell proteins. Rapid brain growth, accelerated synaptogenesis, myelination, astrocyte proliferation, and the organization of multiple neurotransmitter systems characteristic of the developing organism definitely require GCs. Thus, changes in GC activity can be significant to the developing brain. However, for GCs to affect brain development, they must get into the brain and the cell must express MR or GR. In addition, having the receptors is not enough; GCs must also be able to engage the necessary intracellular mechanisms following receptor

binding (reviewed in C. D. Walker et al., 2002). Finally, the impact of GCs on the developing brain also depends on the maturity of other signaling systems and their capacity to interact with GCs. Given that signaling systems have their own development time courses that vary with brain region, the effects of GCs on the developing brain cannot be simply stated. The effects depend on brain region, maturity and activity of other signaling systems, and developmental timing. The interaction of these factors, in addition, varies with species in ways that are not well understood. This poses a major challenge in translating preclinical studies to predictions about GC effects on human development.

As noted earlier, most circulating GCs in the fetus and neonate are unbound and thus potentially biologically active. Furthermore, circulating levels of maternal GCs increase in late pregnancy. This might seem to place the fetal brain at high risk of GC exposure. However, under normal circumstances, in rats and primates high placental levels of the enzyme 11 β -HSD rapidly convert GCs to biologically inert forms (Seckl, Cleasby, & Nyirenda, 2000). There are two known isoforms of 11 β -HSD. Type 1 is bidirectional, capable of converting GCs to inactive forms and then back again, whereas the Type 2 form converts GCs only to less active forms. The expression of the Type 2 form increases with gestation but varies in efficiency among species. In humans, the Type 2 form is the most important, but does not inactivate dexamethasone (DEX) or betamethasone, two GCs used medically to expedite fetal lung maturation in women at risk for premature delivery (Seckl et al., 2000). Thus, in humans, these two medically prescribed GCs pass readily from mother to fetus.

Studies in which endogenous GC was administered to fetal rats show that high levels preferentially affect maturation of neurons in the cerebral cortex, reticular formation, limbic system, and spinal cord. They also globally inhibit neurogenesis, gliogenesis, cell division, and myelination throughout the brain by altering patterns of gene expression (see Table 13.1). GC-induced cell death and cell survival mechanisms are also normally involved in remodeling of neurocircuit structure and function (e.g., Duman, Malberg, & Thome, 1999). The effects of GCs on fetal brain development have been examined in many studies using DEX, because, as noted, this synthetic hormone is used medically in premature infants (reviewed in Matthews, 2000) and bypasses the placental 11 β -HSD system. These studies indicate that DEX can have profound effects on brain development. DEX exposure in the last week of gestation results in adult rats with *reduced* NA content in the hippocampus and cortex and *reduced* NA turnover in the forebrain. However, maturation of the adrenergic sys-

tem is actually advanced in the brain stem and forebrain and there is an overexpression of NA transporter, allowing increased NA recycling. No effect has been detected on adrenergic receptor expression. Interestingly, animals exposed to DEX in utero have increased LHPA function and faulty negative feedback. It is unclear whether DEX-induced modifications of the NA system are involved in producing these changes in LHPA function. Indeed, these changes actually may be due to serotonin. In rats, DEX in the last week of gestation leads to male offspring with increased hypothalamus, hippocampal, and brain stem 5-HT concentrations, probably due to an increase in 5-HT transporter synthesis in the raphe. The combination of increased hypothalamic expression of 5-HT transporter and increased availability of 5-HT are, in part, responsible for the elevated LHPA activity observed in DEX-exposed male offspring. Additionally, impairment in negative feedback in the DEX-exposed fetus may be due to reduced NA levels and 5-HT turnover that may reduce hippocampal GR receptor numbers (reviewed in Matthews, 2000).

Behavioral effects of developmental DEX exposure have also been observed in rodents (reviewed in Matthews, 2000). In mice, a single DEX injection on PND 14 affects fear behavior, memory, and social interactions but not sensory, motor, motivation, and learning performance. In primates, DEX and cortisol administered during fetal development have profound effects on the morphology of the hippocampus. Although behavioral effects have not been reported in rhesus monkeys, in humans DEX exposure beginning before the 10th week of gestation and continued until delivery results in heightened emotionality, unsociability, avoidance, and behavioral problems in children 6 months to 6 years of age (Trautman, Meyer-Bahlburg, Postelnek, & New, 1995). Although many older studies of the effects of antenatal steroids in humans have yielded little evidence of long-term effects, recent studies have demonstrated reduced brain volumes at birth (Modi et al., 2001; Murphy, 2001). Thus, it is clear that GCs have a critical role in brain development.

Development and the Limbic-Hypothalamic-Pituitary-Adrenocortical System in Humans

The developmental neurobiology and physiology of the LHPA system in humans are not well understood. Primates, including humans, do possess a fetal adrenal zone that produces estrogen precursors during gestation (Mesiano & Jaffe, 1997). In humans, this zone involutes over the first 6 postnatal months (Reynolds, 1981). CBG levels are low in the human neonate, increasing over the same age period (Hadjian et al., 1975). Consequently, free

or unbound cortisol levels decrease slightly, and plasma or total cortisol production increases over the first 4 to 6 months after birth. There is also evidence that the adrenal becomes less sensitive to ACTH over the 1st year (Lashansky et al., 1991). Thus, as in the rodent, the pituitary-adrenocortical system continues to develop postnatally. Whether there is a human or primate equivalent of the SHRP is highly uncertain; however, numerous studies show developmental changes in GC responses from the prenatal through the adolescent period. By 18 to 20 weeks of gestation, the fetal LHPA system produces increases in cortisol to aversive stimulation (Giannakoulpoulous, Sepulveda, Kourtis, Glover, & Fisk, 1994). With increased gestational age, basal levels of plasma cortisol and ACTH increase. Healthy, term babies are capable of mounting cortisol and ACTH reactions to the types of perturbations routinely encountered in the newborn period (i.e., physical examinations, heel stick blood draws, and for boys, circumcision; reviewed in Gunnar, 1992).

Cortisol stress responses decrease over the infancy period (e.g., Gunnar, Brodersen, Krueger, & Rigatuso, 1996; Lewis & Ramsay, 1995). On average, it becomes difficult to produce elevations in cortisol to both laboratory and mild medical stressors by the end of the 1st year (see Gunnar & Donzella, 2002), although the absolute change (irrespective of increase or decrease) is similar in the 2nd year as compared to that observed around 6 months of age (Lewis & Ramsay, 1995). It is unlikely that this diminution of cortisol responses is equivalent to the rodent SHRP because it is highly dependent on the immediate presence and support of the caregiver. This was clearly demonstrated in a recent study of toddlers entering child care (Ahnert, Gunnar, Lamb, & Barthel, 2004). During an adaptation period of several days with the mother present, infants in secure attachment relationships showed only very small increases in cortisol over home baseline levels. However, on the 1st day at child care without the mother and continuing for at least the first 9 days, large increases in cortisol were noted for these same infants. Over the course of the preschool years, children become more capable of maintaining basal cortisol levels in the absence of their attachment figures (for review, see Gunnar & Donzella, 2002). A number of mechanisms likely account for the developmental changes in GC responsivity over the infancy and preschool years, including the development of the attachment system and the child's developing social and emotional regulatory competence.

Whereas GC responses tend to decrease over the early childhood years, it has been argued that, with the transition to adolescence, children become more hormonally respon-

sive and thus perhaps more vulnerable to stressors (e.g., Spear, 2000). Several studies have shown both between-subject correlations of age with basal cortisol levels and within-subject increases in basal GCs in children 6 to 17 years of age (e.g., Kiess et al., 1995; Legro, Lin, Demers, & Lloyd, 2003; Netherton, Goodyer, Tamplin, & Herbert, 2004; Shirtcliff et al., in press). Three studies suggest that the most marked increase in basal GCs occurs between 10 and 14 years (Elmlinger, Kuhnel, & Ranke, 2002; Lupien, S. King, Meaney, & McEwen, 2001; Tornhage, 2002); others yield evidence of more gradual, linear increases (Jonetz-Mentzel & Wiedemann, 1993; Lashansky et al., 1991; E. F. Walker et al., 2001). Studies using Tanner staging have suggested that increases in basal levels are observed around Tanner stage 3 (Halligan, Herbert, Goodyer, & Murray, 2004; Netherton et al., 2004). Thus, although basal GC levels do seem to increase from childhood through adolescence, the precise timing and certainly the mechanisms underlying this effect are not well understood.

All of these studies examined salivary or plasma cortisol levels, which do not provide an integrated measure of total cortisol production over the day. Studies using integrated urinary cortisol sampling tend to be at odds with the plasma/salivary studies. Specifically, although 24-hour urinary free cortisol concentrations do increase across the adolescent years, this finding is no longer significant if urine volume (creatinine) and body mass are taken into account (Dimitriou, Maser-Gluth, & Remer, 2003; Gomez, Malozowski, Winterer, Vamvoakopoulos, & Chrousos, 1991; Honour, Kelnar, & Brooks, 1991; Legro, Lin, Demers, & Lloyd, 2003). Lack of evidence for increases in integrated 24-hour cortisol production raises the possibility that increases in basal cortisol with age and/or pubertal status may reflect changes in diurnal patterning of cortisol production rather than overall increases in basal cortisol levels. In this regard, it is noteworthy that most of the studies showing increases in basal salivary or plasma cortisol have collected samples in the morning hours. Furthermore, when both morning and evening samples were obtained, only the morning values were found to correlate positively with pubertal status (Halligan et al., 2004; Netherton et al., 2004). Thus, it is conceivable that changes in basal cortisol may actually reflect the continued maturation of the adult diurnal rhythm that may not become fully mature until around the midpoint of pubertal development.

The vulnerability hypothesis (e.g., Spear, 2000), of course, depends not on basal levels, but on reactivity of the LHPA system. Basal levels may increase with age and/or pubertal status, but it is not clear whether *reactivity* of the LHPA system also increases. There are simply too few stud-

ies that actually have produced elevations in cortisol to address this question. E. F. Walker et al. (2001), however, have interpreted their findings as evidence of increased reactivity to the experience of coming to the lab for testing. Studying children 11 to 18 years of age, they took four salivary cortisol measures during a laboratory stressor paradigm. Cortisol levels *decreased* across the stressor period, suggesting that the initial levels were in fact elevations over baseline. It was these initial levels that were positively correlated with age. Furthermore, several years later, when they brought the children in again for testing, only the initial levels were higher than the child's own initial levels several years before. However, two studies using the TSST modified for children failed to note significant effects of age when children 9 to 16 years were studied (Klimes-Dougan, Hastings, Granger, Usher, & Zahn-Waxler, 2001; Kudielka, Buske-Kirschbaum, Hellhammer, & Kirschbaum, 2004). There is also no evidence that the adrenal becomes more sensitive to ACTH (Dahl et al., 1992; Lashansky et al., 1991) or that CRH infusion elicits overall more cortisol and ACTH with age for children between 6 and 16 years (Stroud, Papadonatos, Williamson, & Dahl, 2004). Thus, if the LHPA axis becomes more reactive during adolescence, the effect is likely to be subtle.

All but one of these studies involved typically developing children. Notably, when risk populations are used, there is no evidence of age changes in cortisol activity, basal or response values, over the transition to adolescence (Dahl et al., 1991; Dorn et al., 2003; Goodyer, Park, Netherton, & Herbert, 2001; Granger, Weisz, & Kauneckis, 1994; McBurnett et al., 1991; McBurnett, Lahey, Rathouz, & Loeber, 2000; Scerbo & Kolko, 1994). It seems possible that if changes in cortisol levels and reactivity with age are generally subtle, these age changes may be readily overwhelmed by the stress of emotional problems or life events in high-risk populations.

Sex Differences and Sex Steroids

Subtle changes in basal levels and/or reactivity of the LHPA system during adolescence, if they exist, may be related to changing sex steroid activity. In rats and in humans, sex differences are apparent at many levels of the LHPA axis. In rats, estrogens have excitatory effects and androgens have inhibitory effects on LHPA function. Thus, in rats, females are the more stress-reactive sex (Critchlow, Liebelt, Bar-Sela, Mountcastle, & Lipscomb, 1963; Le Mevel, Abitbol, Beraud, & Maniey, 1979), and both basal and stress levels of ACTH and GC are high when estrogen levels are elevated (e.g., Bohler et al., 1990). Ovariectomy reduces plasma ACTH and GCs, and replacement of estro-

diol returns ACTH and GCs to normal levels (Burgess & Handa, 1992; Viau & Meaney, 1991). Females also exhibit high levels of CBG (Gala & Westphal, 1965) and CRH (Hiroshige & Wada-Okada, 1973). In addition, gonadal hormones modulate GC metabolism (Grant, Forsham, & DiRaimondo, 1965) and hippocampal MR and GR protein and mRNA levels (e.g., Kerr, Beck, & Handa, 1996; Viau & Meaney, 1996).

In humans, the evidence is fairly consistently the reverse. Men show larger GC and ACTH responses than women to most stressors administered in the laboratory, but are not more reactive than females to systemic or pharmacological stressors (for reviews, see Kirschbaum, Kudielka, Gaab, Schommer, & Hellhammer, 1999; Kirschbaum, Wüst, & Hellhammer, 1992). Men also show larger catecholamine responses than women to stressors such as IQ testing, cognitive-conflict tasks, major examinations, and speech tasks (e.g., Frankenhauser, 1983). The greater male vulnerability to processive stressors has been related to their greater vulnerability to cardiovascular disease and stroke, disorders related to hyperstress reactivity. In contrast, the blunted response of women to stressors has been related to their greater vulnerability to hyporesponsivity disorders, most notably autoimmune and chronic pain disorders (McEwen, 1998). Depression stands in marked contrast to these patterns of sex difference, being associated with hypercortisolism (Nemeroff, 1996) and being more prevalent in women, beginning about midadolescence (Piccinelli & Wilkinson, 2000).

The central gender stress question always has been whether these male-female differences in humans are psychological or physiological. Those arguing for psychological differences note that men and women likely process and cope with stress differently (e.g., Taylor et al., 2000). In addition, they note that most of the stressors examined in human studies have been instrumental or achievement-oriented and that these types of stressors likely threaten the social self in ways that are more central to male self-construals (see Stroud, Salovey, & Epel, 2002). Consistent with this argument is evidence that males compared to females excreted more adrenaline during major university entrance exams. But, among the young women, those who were adrenaline increasers were more likely to have adopted male achievement values, whereas adrenaline decreasers were more likely to place a high value on marriage and parenting and to perceive themselves as fulfilling traditional feminine social roles (Rauste-von Wright, von Wright & Frankenhauser, 1981). More pertinent is evidence that stressors that threaten affiliation are more provocative among women than men. Using participants

age 17 to 23, Stroud and colleagues recently showed that men elevated cortisol to a speech/math stressor, and women elevated cortisol to a social rejection stressor. If replicable, these data suggest serious limitations in the literature on LHPA responses to processive or psychological stressors in human adults—specifically, that the literature is limited to examination of male-biased stressors. We lack adequate evidence of sensitivity to processive stressors in women because we have failed to identify stressors that are ideally designed to threaten core female self-construals.

In contrast, for those taking a physiological perspective on adult sex differences in LHPA reactivity, there is evidence that the sex differences in response to achievement-type stressors varies with the woman's menstrual cycle. Thus, cortisol responses to the TSST do not differ between men and women in the *follicular* phase of their cycles (when estrogen levels rise to their monthly peak), but men respond more than women in the *luteal* phase of the cycle (when estrogen levels are falling; Kirschbaum et al., 1999). These data suggest that failure to control for stage of menstrual cycle may impede our understanding of sex differences in reactivity of the LHPA system in human adults. According to the physiological argument, we would not expect to observe sex differences in basal cortisol at any point in childhood, but we would expect to observe sex differences in responses to processive stressors beginning around the midpoint in puberty. The child data are relatively consistent with these predictions. Of over 20 studies of basal cortisol that included boys and girls, we found only three that reported significant sex differences, one showing higher levels for girls (Smider et al., 2002) and two for boys (Elmlinger et al., 2002; Jonetz-Mentzel & Wiedemann, 1993). Studies of GC responsivity to stressors similarly report few sex differences in infancy and early childhood. One study of newborns did report larger increases for boys (M. Davis & Emory, 1995), and a study of peer entry stress in preschoolers reported larger increases for girls (Sethre-Hofstand, Stansbury, & Rice, 2002). There is some suggestion, however, that studies involving competitive challenges might produce larger GC responses in prepubertal boys than girls (Donzella, Gunnar, Krueger, & Alwin, 2000; Jansen et al., 1999; Kertes & Gunnar, 2004). Furthermore, one study noted that prepubertal boys showed larger GC responses to CRH than did girls (Dahl et al., 1992). However, overall, prior to adolescence, sex differences in GC activity tend to be infrequently reported.

Sex differences in response to processive stressors appear to emerge in adolescence. Male adolescents taking university entrance exams exhibit cortisol increases, but females typically do not (Frankenhaeuser et al., 1978). Boys

between 14 and 16 years of age produce larger cortisol responses than girls to a psychosocial stressor, but this was not the case among younger, 10- to 13-year-old children in the same study (Klimes-Dougan et al., 2001). Among 13- to 17-year-old adolescents, boys have also been observed to exhibit a larger ACTH response to CRH administration (Dorn et al., 1996; although see Stroud et al., 2004). Thus, in a number of studies of typically developing children, boys begin to exhibit larger LHPA responses than girls around the midpoint in puberty. As noted, however, the types of stressors examined to date may be male-biased, involving threats to instrumental competence. We simply do not know whether girls respond more to threats to affiliative competence (i.e., social rejection) and, if so, whether such sex differences in stress reactivity, if they exist, emerge or change from childhood through adolescence.

PSYCHOPATHOLOGY

Adverse early experiences in human and nonhuman primates increase the variability of LHPA functioning, in some individuals producing hyperreactivity and in others, seemingly, hyporesponsivity. This may partly reflect interactions between genetic dispositions to particular disorders and experience. Prior to reviewing the early experience literature, we provide a brief overview of patterns of LHPA activity in three types of behavior disorders associated with adverse early rearing environments: disruptive behavior disorder, anxiety disorders, and depression.

Disruptive Behavior Disorders

Although there are several models of the processes underlying Oppositional Defiant Disorder (ODD) and Conduct Disorder, referred to collectively as disruptive behavior disorders (DBD), they all revolve around constructs of underarousal and underreactivity (Burke, Loeber, & Birmaher, 2002). The general idea is that children at risk for DBD are underreactive to threat stimuli, resulting in impaired avoidance learning and underarousal, which may encourage sensation seeking as a means of increasing arousal. None of the models is complete, and most assume that they may apply only to subgroups of children with DBD (Burke et al., 2002; McBurnett & Lahey, 1994).

Consistent with models of underarousal, low basal or pretest cortisol has been reported in a number of studies, most using variants of the following protocol. Children arrive for testing in the morning, often around 9 A.M. A

saliva sample is taken, after which the child is subjected to a mild stressor task, and a second saliva sample is taken at the end of testing 30 to 40 minutes later. Typically developing children exhibit high cortisol levels at pretest with decreasing levels over the testing period. In contrast, DBD children or those at high risk for DBD have low cortisol levels at pretest that do not change over the testing period (Hardie, Moss, Vanyukov, Yao, & Kirillovac, 2002; King, 1998; Moss, Vanyukov, & Martin, 1995; Moss, Vanyukov, Yao, & Kirillovac, 1999). This pattern has been observed in both boys and girls (Hardie et al., 2002; Pajer, Garner, Rubin, Perel, & Neal, 2001). Even in studies that have failed to obtain group differences in cortisol between DBD and control children, disruptive behavior symptom counts have correlated with lower early morning cortisol levels (Pajer, Gardner, Kirillovac, & Vanyukov, 2001; Scerbo & Kolko, 1994; Vanyukov et al., 1993). Although most cortisol studies of DBD children have sampled cortisol in the early morning, not all have. McBurnett and colleagues (McBurnett, Lahey, Frick, et al., 1991; McBurnett, Lahey, & Rathouz, et al., 2000) have reported lower cortisol levels for DBD children, despite not controlling for time of day.

Perhaps more significant, several studies have demonstrated that low cortisol levels predict later disruptive behavior problems. Granger, Weisz, and McCracken (1996) reported that clinic-referred 9- to 16-year-olds who had low cortisol levels at the beginning of a late-afternoon laboratory test displayed more delinquency at follow-up testing several months later. Similarly, in another study (van de Wiel, van Goozen, Matthys, Snoek, & van Engeland, 2004), 8- to 13-year-old boys with DBD who had cortisol levels below the median had higher externalizing, ODD, and overt aggression scores at a 9-month follow-up assessment than did boys with cortisol levels above the median. Finally, in a study of several hundred adolescent boys, resting cortisol levels assessed when the boys were between 10 and 12 years of age were negatively correlated with self-reported aggression and positively correlated with constraint, control, and harm avoidance 5 years later (Shoal, Giancola, & Kirrilova, 2003). Thus, DBD children and those who develop DBD symptoms appear to have lower cortisol levels than do nondisordered children. Low basal or pretest cortisol would be consistent with an underarousal hypothesis, and through impairment of permissive actions of GCs might reduce responsiveness of other stress-sensitive systems (e.g., brain monoamines).

What is not as well established is whether low reactivity of the LHPA system is associated with DBD. To examine the underreactivity hypothesis requires that experimentally

imposed stressors elevate cortisol in the control or comparison group. To date, only two studies have met this criterion (van Goozen, Matthys, Cohen-Kettenis, Buittelaar, & van Engeland, 2000; van Goozen et al., 1998). Van Goozen and colleagues exposed severely disordered DBD children and controls to a task during which a peer (on audiotape) denigrated their performance. When the paradigm was conducted during the morning hours, the task prevented the normal decrease in cortisol among the typically developing and DBD children. When performed in the afternoon hours, typically developing but not DBD children exhibited significant cortisol increases. In addition, in both the morning and afternoon studies, DBD children exhibited lower heart rate and skin conductance than did the typically developing children. Of particular importance, in a recent follow-up study, these researchers (van del Wiel et al., 2004) examined the effectiveness of treatment for DBD children as a function of cortisol reactivity to their paradigm. Treatment included medication and individual and family therapy. Children with DBD who exhibited no cortisol response to their stressor paradigm also failed to show improvement in DBD symptoms 9 months after the onset of treatment, whereas those who did show a cortisol response did show improvement. Thus, there is some evidence from at least this research group that DBD, and perhaps especially DBD that is resistant to treatment, is associated with low GC responsivity.

However, not all DBD children exhibit low cortisol levels. In fact, several researchers have noted that the combination of DBD and anxiety disorders is associated with high rather than low cortisol activity relative to controls. Thus, McBurnett and colleagues (1991) found higher levels of cortisol among comorbid (DBD + anxiety) children than in DBD-only children. In both of their studies, van Goozen and colleagues (1998, 2000) found that DBD children, but not normal controls, who showed a cortisol response to the stressor task were more anxious and depressed than those who did not respond. Finally, Scerbo and Kolko (1994) found that parent reports of internalizing problems were positively correlated with cortisol levels in their DBD children. Thus, across all of the studies that included measures of anxiety, low cortisol levels were typically observed *only* for those disruptive children who were not clinically anxious. McBurnett and Lahey (1994) caution that to clarify the relations between cortisol and disruptive behavior problems, we may need to distinguish between aggressive (undersocialized Conduct Disorder) and nonaggressive forms of the disorder. The 10- to 12-year-old boys studied by McBurnett and colleagues (1991) who had the lowest cortisol levels were also described by

peers as the meanest and by adults as having the most aggressive symptoms. Pajer and colleagues (2001) noted a similar, but nonsignificant, difference between the aggressive and nonaggressive DBD girls.

It is unclear why at least some subtypes of DBD children might exhibit low basal cortisol levels and possibly hyporeactivity of the HPA axis. Studies of DBD children's response to serotonergic challenges have shown that these children exhibit blunted cortisol reactions to fenfluramine (Soloff, Lynch, & Moss, 2000) and sumatriptan (Snoek et al., 2002), suggesting that serotonergic regulation of the LHPA system is compromised. Monkeys carrying the short version of the serotonin transporter allele are especially vulnerable to disturbances in the early caregiving environments that elevate cortisol (Bennett et al., 2002). Studying children of substance-abusing fathers, investigators have hypothesized that low cortisol levels in these children may be the product of disturbances in their family environment (Hardie et al., 2002; Pajer, Gardner, et al., 2001). Thus, low cortisol levels may be the result of down-regulation of the axis following periods of elevated cortisol. Unfortunately, none of the studies of DBD children or those at risk for DBD problems has started assessing children's neuroendocrine and autonomic reactivity during the first years of life.

In this regard, it is useful to examine relations between disruptive behavior and cortisol activity in community samples of primarily nondisordered children. For school-age and older children, the evidence fairly consistently points to significant associations between low cortisol and more externalizing-type behaviors (e.g., Flinn & England, 1995; Spangler, 1995; Tennes & Kreye, 1985; Tennes, Kreye, Avitable, & Wells, 1986). Using a very large sample of 6- to 16-year-old children, Shirtcliff and colleagues (in press) applied latent state-trait modeling techniques to identify the trait component of early morning cortisol production. Then they examined whether the trait component was associated with either internalizing or externalizing problem behavior in the nonclinical range. For boys, but not girls, they found a significant negative relation between trait cortisol shortly after waking and externalizing problems.

Studies of typically developing children under the age of 7, when oppositional and aggressive behaviors are more normative, have yielded weaker and more mixed results. Lower cortisol levels for more aggressive children have been noted in two studies (de Haan, Gunnar, Tout, Hart, & Stansbury, 1998; Hart, Gunnar, & Cicchetti, 1995). Larger, rather than smaller, cortisol reactivity among more aggressive children to new peer situations was noted in three

studies (de Haan et al., 1998; Dettling, Gunnar, & Donzella, 1999) but not in other similar studies (Bruce, Davis, & Gunnar, 2002; Dettling, Parker, Lane, Sebanc, & Gunnar, 2000; Gunnar, Tout, de Haan, Pierce, & Stansbury, 1997). Thus, during the toddler and preschool years, when aggression and oppositional behavior is observed at relatively high frequencies, the relationship between these behaviors and cortisol is unreliable in typically developing children. However, children who persist in more aggressive, oppositional behavior during the school-age and adolescent years, even though their behavior is within the nondisordered range, do appear to have lower basal and perhaps less reactive LHPA systems.

Anxiety Disorders

Pathological anxiety in animals and humans may reflect an exaggeration of normal anticipatory LHPA responses (Rosen & Schulkin, 1998). This argument builds on related models of the LHPA system's role in the pathophysiology of affective disorders (e.g., Gold, Goodwin, & Chrousos, 1988). Anticipatory anxiety involves phasic immobility or freezing, autonomic changes (e.g., increased sympathetic discharge), increased neuroendocrine activity (e.g., elevated levels of GCs), heightened reflexive responses to sensory stimuli (e.g., fear-potentiated startle), hypoanalgesia, and increased urination and defecation (Rosen & Schulkin, 1998). In the presence of elevated GCs and CRH, a cascade of biomolecular events that include increased expression of immediate-early genes (Makino, Gold, & Schulkin, 1994) increases the sensitivity of central fear circuits, heightens anxiety to distal danger cues, and supports the transition from normal to pathological anxiety.

A number of studies of anxiety-disordered children reveal elevations in basal GC levels (Carrion et al., 2002; DeBellis, Baum, et al., 1999; Klimes-Dougan et al., 2001; however, see Martel et al., 1999 for a counterexample). In addition, there is also growing evidence that clinically anxious children are hyper-GC-responsive to some types of stressors, including air puff startle (Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002) and mother-child conflict discussions (Granger, Weisz, et al., 1994), although such associations have not always been found (Dorn et al., 2003; Martel et al., 1999). Cortisol reactivity has also been shown to predict subsequent anxiety symptoms among clinic-referred adolescents (Granger et al., 1996). Finally, as discussed earlier, anxiety plus DBD is associated with higher cortisol activity than observed among control and nonanxious DBD children.

If hyperresponsivity of the LHPA axis constitutes a diathesis for the development of anxiety disorders, then we should find evidence of heightened LHPA axis activity in extremely temperamentally inhibited and/or socially reticent children who are at risk for the development of these disorders (Rosenbaum et al., 1993). However, because novel situations should elevate cortisol in nonanxious as well as anxious individuals, this may be difficult to demonstrate. Many studies of adults have shown that GC elevations are larger the first time individuals confront a challenging or threatening event and diminish markedly with repetition (as reviewed in Kirschbaum & Hellhammer, 1989). Elevating GCs in anticipation of challenge thus is not pathological but instead is an adaptive function of the LHPA axis (Rosen & Schulkin, 1998; Sapolsky et al., 2000). In studies of adults and animals, individuals who exhibit the largest increases in cortisol under normative conditions of uncertainty are sometimes more dominant and assertive, rather than shy or socially reticent (e.g., Golub, Sassenrath, & Goo, 1979; Hellhammer, Buchtal, Ingmar, & Kirschbaum, 1997). Thus, whereas anxious individuals may exhibit anticipatory cortisol reactions, so may competent, assertive individuals. However, as most individuals should show habituation of the LHPA axis response upon repetition of the same stressor, we might find evidence that failure to habituate is associated with risk for developing anxiety and depression.

Indeed, this conclusion appears to be the thrust of work by Pruessner and colleagues (1997). Personality differences among adult subjects did not predict elevations in cortisol to the first stressor trial. However, although most subjects habituated on subsequent trials, responses on these trials were significantly and highly correlated with two risk factors in the etiology of affective disorders: low self-esteem and external locus of control. In a similar vein, van Eck and colleagues (van Eck, Berkhof, Nicolson, & Sulon, 1996; van Eck, Nicolson, Berkhof, & Sulon, 1996) demonstrated that high trait-anxious individuals were more likely to exhibit cortisol elevations to familiar daily hassles (i.e., being late for the bus, a disagreement with a coworker). This was the case even though high trait anxiety was not associated with larger GC responses the first time individuals were subjected to a laboratory stressor (i.e., the TSST). Taken together, these adult findings suggest that continuing to activate the LHPA axis to familiar stressors, rather than exaggerated activation to a novel stressor, may form part of the diathesis for the development of pathological anxiety. If so, then during development, cortisol activity might correlate less often

with inhibited, socially reticent temperament when children are tested responding to novel, unfamiliar stressors than when they are tested reacting to familiar challenges at home or school.

There is some support for this hypothesis. Young children who exhibited more facial expressions of fear to emotion-eliciting laboratory events did not have higher cortisol levels in the laboratory, but did at home (Buss et al., 2003). Likewise, in another study, shy/anxious temperament predicted home but not school levels of cortisol during the initial weeks of preschool (de Haan et al., 1998). Similarly, Schmidt and colleagues (Schmidt & Fox, 1998; Schmidt et al., 1997) did not find that extremely shy, inhibited children produced higher GC responses to a laboratory stressor, but did have higher home early morning GC levels. Kagan, Reznick, and Snidman (1987) reported similar results.

Using new peer group settings, several researchers have noted higher cortisol levels among more anxious, introverted children, but only once the play group setting was familiar (e.g., Granger, Stansbury, & Henker, 1994). In one study of children entering a new playgroup, anxious children did have high cortisol levels, but so did the most socially outgoing children (Legendre & Trudel, 1996). In several studies of children starting new school years, we (Bruce et al., 2002; E. Davis, Donzella, Krueger, & Gunnar, 1999) noted that by the 5th day of school, a time when the situation should still be novel especially for first-grade children, exuberant or extroverted children had higher cortisol levels relative to weekend baseline days earlier in the day prior to and during school. In contrast, shy, inhibited children exhibited elevated bedtime cortisol levels hours after they had returned home. Thus, increasing cortisol levels to novel, uncertain stressors may not be unique to shy, inhibited children, but, shy, inhibited children may be less likely to habituate cortisol responses as the situation becomes more familiar, and they may be less able to turn off the cortisol response once they have left the novel situation.

Studies examining relations between fearful temperament and physiological reactivity typically have used laboratory challenges to elicit wary or fearful behavior (e.g., Kagan et al., 1987). Fussing, crying, seeking proximity with attachment figures, and withdrawing from or avoiding contact with the threat stimuli are then used to measure fear. One reason associations between fearful behavior and cortisol may be low is that these behaviors also reflect active attempts to manage or control threat. As long as the individual possesses responses to cope with threat, we would not expect to see elevations in GCs. This may be why several researchers now report that freezing may be the fear

behavior that is the most closely correlated with increases in GCs and in sympathetic reactivity (Buss, Davidson, Kalin, & Goldsmith, 2004; Gunnar & Nelson, 1994). Freezing in situations where the child has many avenues available to exert control over the threat may be particularly noteworthy (Buss et al., 2004).

We cannot tell from these studies whether cortisol activity also predicts the development of anxious, internalizing problems. Some evidence suggests that it may. Essex and colleagues (Essex, Klein, Eunsuk, & Kalin, 2002; Smider et al., 2002) obtained salivary cortisol samples at home when the children were 4.5 years of age, and these measures predicted internalizing problems in kindergarten a year later and both internalizing and externalizing problem behavior in first grade. Somewhat similar findings have been reported in studies of young adolescents (Granger et al., 1996; Susman, Dorn, & Chrousos, 1991; Susman, Dorn, Inoff-Germain, Nottelman, & Chrousos, 1997). Notably, however, when behavior and cortisol are both used to predict later behavior problems, behavior is the better predictor (Granger et al., 1996; Susman et al., 1991). However, because cortisol levels are often based on only one or two assessments, the greater predictive value of behavioral measures may reflect their greater statistical reliability. Finally, when family process variables are included in studies of cortisol and internalizing problems, the family measures predict both cortisol levels and internalizing symptoms (Granger et al., 1998).

Depression

There is typically high comorbidity between anxiety and depression. We consider depression here separately from anxiety, however, because so much of the LHPA research on psychiatric disorders has focused on Major Depressive Disorder (MDD), often using anxiety-disordered individuals as a comparison group. Indeed, disturbance in LHPA regulation in adults with MDD is among the most reliable findings in biological psychiatry (see review, Pariante, 2003). Alterations are observed in both the diurnal rhythm and negative feedback regulation of the axis. In many adult MDD patients, basal levels of cortisol and ACTH remain high throughout the day, resulting in hypercortisolemia and a loss of the normal diurnal rhythm. Fast-feedback regulation of the axis is impaired, resulting in larger and more prolonged elevations to stressors and failure to suppress cortisol to DEX. Chronic CRH drive and high cortisol levels produce down-regulation of pituitary ACTH and thus blunted ACTH responses to CRH challenge. Blunted growth hormone responses to a variety of challenges, in-

cluding stimulation with growth hormone releasing hormone (GHRH), are also frequently observed, perhaps reflecting chronic CRH drive at the level of the pituitary (Ryan, 1998). These results meet several of the criteria for dysregulation outlined earlier in this chapter. Indeed, several prominent theories of the etiology of depression focus on dysregulation of the LHPA axis and/or of CRH (e.g., Holsboer, 2000; Nemeroff, 1996).

There have been a number of excellent reviews of LHPA axis functioning in child and adolescent depression (e.g., Goodyer, Park, & Herbert, 2001; Ryan, 1998). Thus, we only briefly review this area of research. Studies using ambulatory measures of salivary cortisol in depressed adolescents often yield evidence of elevated GC levels, similar to results obtained for adults (Goodyer, Herbert, & Altham, 1998; Goodyer, Herbert, Moor, & Altham, 1991). Higher cortisol levels and higher cortisol: DHEA ratios may also predict longer illness duration (Goodyer et al., 1998). Nonetheless, fewer MDD adolescents than MDD adults exhibit evening distortions of the LHPA rhythm (Dahl et al., 1991; Forbes, Williamson, Ryan, & Dahl, 2004; Goodyer et al., 1998). In addition, evidence for hypersecretion of GC in early-onset depression is sparse when depressed children and adolescents are studied under controlled laboratory conditions. Under highly controlled sleep-laboratory conditions, most MDD school-age and adolescent children exhibit normal diurnal patterns of cortisol and ACTH production relative to carefully screened, supernormal controls (e.g., Dahl et al., 1991).

There are many other indications that MDD in children and adolescents is less associated with endogenous dysregulation of the LHPA axis than it is in adults. Nonsuppression of cortisol to DEX is rare in MDD children and adolescents, and ACTH and cortisol responses to CRH are also typically normal, at least in depressed children who have not also been physically abused (for review, see Ryan, 1998). Perhaps important, however, MDD in children, as in adults, is associated with blunted growth hormone responses to provocative challenges as well as to stimulation by GHRH, and this blunted response appears to continue after recovery from the illness (reviewed in Ryan, 1998). As noted, this may reflect the impact of chronic CRH drive. Failure to observe alterations in the axis at the level of the pituitary and adrenal in depressed children and adolescents may reflect the resilience of the axis to endogenous dysregulation during childhood. Furthermore, this would suggest that such endogenous dysregulation might become more apparent by late adolescence or with more chronic, recurrent illness (see also Kutcher et al., 1991).

Given that abnormalities in LHPA axis functioning are less characteristic of early-onset depression than adult-onset depression, it would be surprising to find that pre-morbid activity of the axis predicts the development of depression in high-risk samples. Nonetheless, there is some evidence to this effect. Luby and colleagues (2003) found that anhedonic preschoolers exhibited increases in cortisol to mild laboratory challenges that were not noted among children with more typical affective dispositions. Among adolescents, highly variable early morning basal cortisol levels across days predicted which adolescents would experience their first bout of clinical depression over the next months (Goodyer, Herbert, Tamplin, & Altham, 2000). Specifically, when 4 days of 8 A.M. and 8 P.M. cortisol were obtained, adolescents who spiked (exhibited at least one value in the upper 10% of the distribution of values) were 7 times as likely to develop depression over the next few months. This effect was specific to the morning cortisol samples (see also Halligan, Herbert, Goodyer, & Murray, 2004). Loneliness has also been shown to be a correlate of higher ambulatory cortisol levels in typically developing, low-risk adolescents, and for adolescents at school, being alone at the time of sampling rather than being with friends has been associated with increasing cortisol levels (Adam, 2002). Thus, although an endogenous dysregulation of the LHPA axis does not appear to be present in most children with depression, heightened cortisol reactivity and higher levels associated with loneliness suggest that activity of the LHPA system may contribute to the etiology of depression in children and adolescents. However, in many of these studies of children at risk for depression, the role of anxiety in potentially disturbing activity of the LHPA system was not clearly ruled out. Thus, in some of these studies of at-risk children, high anxiety and LHPA axis disturbances may be indicating risk for the development of depression.

Summary of Limbic-Hypothalamic-Pituitary-Adrenocortical Activity in Child Clinical Disorders

This brief review of the literature on LHPA associations with clinical disorders and subclinical behavior problems in children yields evidence of association with both hypo- (e.g., DBD without anxiety) and hypercortisol activity (anxiety and, to some extent, depression). Because in humans early adverse experiences tend to increase rates of both disruptive and anxious/depressed symptoms, we might expect the impact of early experiences on LHPA functioning to be filtered through individual vulnerabilities to different patterns of disordered functioning. There

is little evidence for this in the rodent research that spawned much of this field of inquiry. However, because the preclinical studies have been conducted on highly inbred strains, we might expect less evidence of the multifinality (different end points associated with similar experiences) typically observed in human studies of early experiences.

EARLY EXPERIENCES AND STRESS REACTIVITY AND REGULATION

Studies of the impact of early experience on the LHPA system have important implications for developmental psychopathology. Here we first review the detailed work conducted in rodents and then examine the implications of this work for our understanding of primate development, including the development of young children.

Rodent Studies

The long history of early experience stress studies in rats provides the basis for attempts to understand how variations in care early in life may impact individual differences in stress resilience and vulnerability to psychiatric disorders. There have been many recent and excellent reviews of this literature (e.g., Cirulli & Alleva, 2003; Graham, Heim, Goodman, Miller, & Nemeroff, 1999; Sanchez, Ladd, & Plotsky, 2001); thus, we only very briefly outline the general findings. A number of early experience paradigms have been used in the rat. Most involve some form of maternal separation. *Handling* involves very brief (3 to 5 minutes) daily removal of the pup from the mother and nest. *Separation* involves longer periods, ranging from 3 hours daily to 6 to 24 hours one or more times prior to weaning. Over 20 years ago, Levine (1975) argued that these manipulations produce their effects, at least in part, by altering mother-pup interaction (but see also Denenberg, 1999). Current evidence suggests that the critical components of maternal behavior affected by early experience manipulations center on feeding interactions. Specifically, they center on how much the mother licks and grooms her pups (typically occurring in conjunction with nursing bouts) and how well she assumes the nursing posture (arched back). Handling seems to stimulate increased licking/grooming and arched-back nursing (LG-ABN), although in some strains (but not in others), separation reduces these aspects of maternal behavior. In strains where these aspects of maternal behavior are not reduced by separation, hyperresponsivity of the LHPA axis is not observed. Similarly, spontaneous variations in LG-ABN among mother rats have also been associated with long-term

effects on offspring similar to those observed in handling (high LG-ABN) and separation (low LG-ABN). The effects of handling are greater in the 1st than in the 2nd postnatal week. In addition, 24 hours of maternal separation has opposite effects when performed at the end of the 1st compared to the 2nd postnatal week. Both of these findings suggest sensitive periods for effects on the LHPA system early in postnatal development in the rat.

Handling and high LG-ABN produce offspring who later in life are less fearful and exhibit lower CRH activity in the hypothalamus and amygdala, increased GR in the hippocampus, and better containment of the GC response. They also evidence enhanced functioning of the noradrenergic, dopamine, and serotonin system and increased synaptogenesis in various regions of the brain (see review articles cited earlier). Maternal separation and low LG-ABN produce the opposite: high fearful offspring with heightened CRH and LHPA reactivity. Of particular importance, the early experience manipulations in rodents appear to affect responses to processive stressors more than systemic stressors, thus implicating corticolimbic components of the stress-emotion system. GCs may not mediate the effects of maternal separation, as suppression of GCs has no ameliorating effects on pups separated for 24 hours. Instead, there is evidence that CRH operating through CRHR1 may contribute to the effects of these early experience manipulations. In addition, although the effects of early experience manipulations on GR may be permanent, exposing juvenile rats to environmental enrichment can reverse many of the other behavioral and neurobiological effects of maternal separation. This suggests that in the rat, postweaning manipulations continue to shape neural components of the stress-emotion system (Francis, Diorio, Plotsky, & Meaney, 2002).

Because so much of the data on early experiences and later stress reactivity and regulation comes from rat models, we face a number of challenges in translating this literature to human or, for that matter, primate development. Critically, gestational time varies such that birth occurs at a different point of neurobiological development: 3 weeks for the rat, 7 months for the monkey, and 9 months for the human. Rats are weaned at 21 to 22 days of age in the laboratory (28 days in the wild), monkeys at 1 year, and 2 to 3 years of nursing is not uncommon for human infants in hunter-gatherer cultures. Based on first signs of reproductive ability, rats are juvenile between 35 and 45 days of age, nonhuman primates around 3 to 4 years of age, and humans until the 2nd decade of life. The central nervous system is much more immature in the rat at birth than in the human and nonhuman primate, although at this time, there is no

agreed upon method of identifying corresponding developmental periods of neural plasticity among species. Nonetheless, there is reason to believe that the 1st postnatal week in the rat likely corresponds to prenatal development in humans (Dobbing, 1981; Vazquez, 1998). Postnatal experiences should operate primarily on brain regions that develop after birth. Because at birth the HPA system is more mature in the primate than in the rat, we might expect that postnatal effects on the stress-emotion system in primates would be less apparent in the HPA system than in the corticolimbic pathways influencing stress reactivity and regulation.

Nonhuman Primate Studies

Early experience research in nonhuman primates has largely progressed through the lens of attachment theory. Accordingly, the mother-infant relationship has been conceptualized as a social buffer against stress (Bowlby, 1969; Suomi, 1995). Maternal buffering describes situations in which the infant may be behaviorally distressed but physiological stress responses are attenuated. For example, capture and handling elicits intense behavioral distress, but when mother and infant are immediately reunited, cortisol responses are minimal (Levine & Wiener, 1988). Although there is as yet no clear evidence of an SHRP in the monkey infant, maternal buffering may serve the same function, reducing the likelihood of high GC exposure during periods of rapid brain development. In primates, physical contact is critical for the development of the attachment relationship (Harlow, Harlow, & Suomi, 1971). However, monkey infants can also use distal modes of communication with mother to buffer LHPA and NA responses to separation (e.g., Bayart, Hayashi, Faull, Barchas, & Levine, 1990). The natural ecology of most primate species is social. Mother and infant live in troupes that include other mothers and infants, adult males, and the infant's older siblings. Species differ in how often the infant is parented by other members of the troupe, a phenomenon termed *alloparenting* or *aunting*. Although the availability of alloparents does not prevent elevations in cortisol to maternal separation, it does result in a more rapid termination of the GC response and a reduction in the likelihood of despair reactions (I. C. Kaufman & Rosenblum, 1967; Levine & Wiener, 1988). Thus, in primate infants, maternal buffering is not restricted to physical contact between mother and infant and is a function that can be provided to some extent by other nurturing conspecifics.

Separation confronts the infant with two conflicting challenges: Reestablish contact and avoid attack or preda-

tion. Two stages of separation response have been described: *protest*, or the period of active searching, and *despair*, a period of passivity and withdrawal (Bowlby, 1973). Although once described as a necessary biphasic process following maternal loss (Bowlby, 1973), infant behavior during both phases is affected by the context of separation. Protest appears to be related to pre-separation factors (e.g., Gunnar, Gonzalez, Goodlin, & Levine, 1981) and cues signifying predation/attack (Kalin, Shelton, Rickman, & Davidson, 1998). Despair appears to be affected by the presence of alloparents and the degree of social threat confronting the infant in the mother's absence (Hinde & Davies, 1972). Separation thus is not a unitary phenomenon (Kraemer, Ebert, Schmidt, & McKinney, 1991). Its complexity may help explain why protest behaviors at times are inversely related to separation-induced LHPA activity and why during prolonged and/or repeated separations protest behaviors are sometimes reduced, while LHPA continues or sometimes increases (e.g., Coe, Glass, Wiener, & Levine, 1983). Levine and Wiener (1988) have argued that protest reflects the active attempts to cope with separation, and LHPA responses reflect failed coping. An alternative, but not mutually exclusive, explanation is that protest reflects operation of the attachment system, and LHPA activity reflects actions of central fear/anxiety systems.

Support for this latter argument comes from studies by Kalin and his colleagues. In rhesus infants, administering exogenous opiates during separation reduces protest behavior but not GCs or defensive behaviors (e.g., freezing and threatening experimenters; Kalin, Shelton, & Barksdale, 1988). In contrast, intraventricular CRH administration during separation increases GCs and defensive behavior but not protest (Kalin, Shelton, & Barksdale, 1989; Kalin, Shelton, & Turner, 1992). In rhesus infants, there is a close correspondence between defensive behaviors (e.g., freezing) and LHPA activity. LHPA activity in rhesus infants is also associated with greater right frontal EEG asymmetry, suggesting corticolimbic organization of defensive, withdrawal behaviors (Kalin et al., 1998). Combined, these data argue that separation can produce fear in infant primates, and that when it does, we see marked elevations in LHPA activity and defensive behaviors, perhaps orchestrated, at least in part, by extrahypothalamic CRH. How much the infant protests, however, is often uncorrelated with activity of the LHPA axis and may be organized along different neurobiological pathways. There is evidence of a similar dissociation between separation-induced crying and cortisol elevations in human infants (e.g., Spangler & Schieche, 1998).

Whereas repeated separation in rats produces hypercortisolism, in monkeys it may reduce LHPA activity. Infant squirrel monkeys do not exhibit habituation of the LHPA response to repeated 6-hour separations, even with as many as 80 trials (Hennessy, 1986). However, several years later, previously separated juveniles demonstrate blunted GC and NA responses to social isolation stress (Levine, Lyons, & Schatzberg, 1997). Repeated, daily separations of several hours in marmosets during the 1st month of life lower basal cortisol near the peak of the circadian cycle while increasing fearful, anxious behaviors (Dettling, Feldon, & Price, 2002). In contrast, in squirrel monkeys, 1 hour of separation weekly for 10 weeks had the opposite effect, reducing clinging and increasing exploration of a novel environment and blunting LHPA responsivity (Lyons et al., 1999; Parker, Buckmaster, Schatzberg, & Lyons, 2004). Lyons and colleagues (e.g., 1999) suggest that brief separations in monkeys may function like handling in rats. However, a recent study of repeated, unpredictable separations in rhesus infants questions this conclusion (Sanchez et al., in press). Monkey infants typically spend less time in close proximity to mother with age; however, infants who experienced the series of unpredictable separations showed the reverse: *increases* in proximity with age. Evidence of heightened stress reactivity was noted, although this was more apparent for females in cortisol reactivity and males in heightened acoustic startle reactions. Of importance for comparison with human studies of early trauma and deprivation, both males and females exhibited disturbances in diurnal cortisol production, although the disturbances varied by sex, with males showing a shallower rhythm over the morning hours and females exhibiting a flatter rhythm from morning to evening. Thus, repeated separation paradigms produce alterations in fear/anxiety and LHPA activity in monkey infants. Nonetheless, these changes do not always suggest heightened stress reactivity. In some cases, they appear to produce blunted responsivity to subsequent stressors. Whether these differences reflect species differences, differences in developmental timing, and/or differences in the supportiveness of the separation environment (e.g., presence of alloparents) is not yet clear. These findings do, however, raise critical questions about how best to translate the rodent findings to primates, including humans.

The challenge of translating the rodent findings is also demonstrated by work on prolonged separations in infant monkeys. Separations of several days or weeks increase fearful, anxious behavior in monkey infants. Tested months and years after the separation experience, juvenile rhesus who were separated once or twice in infancy were found to be more neophobic and behaviorally reactive than

never-separated animals (Spencer-Booth & Hinde, 1971). These effects were greater when the infant was left in the social group than when it was removed and the mother remained in her familiar surroundings (Hinde, Leighton-Shapiro, & McGinnis, 1978). Continuing the theme of maternal mediation of separation effects, Hinde argued that removing the mother from the social group was more devastating than removing the infant because, in the former case, the mother had to ignore the infant and reestablish her social position in the troupe upon her return. However, there is also evidence that leaving the infant in the social group, if it is not adopted by another female, also results in prolonged GC increases and other neurobiological disturbances (Laudenslager et al., 1995; Reite, Harbeck, & Hoffman, 1981). In contrast, if infant rhesus monkeys are placed alone in single cages during separation, GC levels return to near baseline within 24 hours (Gunnar et al., 1981). These findings are consistent with Kalin's (Kalin, Shelton, & Barksdale, 1988) argument that LHPA activity during separation reflects the degree of ongoing threat in the separation environment. Despite evidence of continued elevations in GCs during prolonged separations, however, there is little evidence of long-term changes in the LHPA axis (Capitanio, Rasmussen, Snyder, Laudenslager, & Reite, 1986).

In addition to separation, the effects of several aberrant rearing environments have been studied, including total and partial social isolation rearing, surrogate-peer rearing, and peer-only rearing. Sensitive periods have been demonstrated for behavioral abnormalities with deprivation during the first 6 months, resulting in more drastic effects than similar deprivation periods later in life (for review, see Kraemer, 1992). As in the research on separation, despite marked increases in bizarre behavior and anxious, neophobic reactions, long-term effects on the LHPA axis rarely have been observed. Considering social isolation rearing first, although there is evidence of marked aberrations in the coordination of central monoamine systems (Kraemer, Ebert, Schmidt, & McKinney, 1989), isolate-reared monkeys do not show increased LHPA reactivity (Meyer & Bowman, 1972; Sanchez, Young, Mathys, Plotzky, & Insel, 1999). Indeed, normalizing experience in these paradigms tends, if anything, to increase basal GCs and autonomic responsivity to stressors (Hill, McCormack, & Mason, 1972; Wood, Mason, & Kenney, 1979). Structural and neurochemical studies also have failed to reveal effects on the LHPA system (Sanchez et al., 2001). Changes have *not* been detected in BNST, in the number of hypothalamic dopaminergic neurons, the density of CRH neurons in the PVN or in CRH or AVP or their receptors in the hypothalamus, including the mpPVN (Sanchez et al.,

1999). Failure to find effects on the LHPA axis may reflect the greater maturity of this system at birth in the primate as compared to the rodent. Nonetheless, corticolimbic areas important in the regulation of fear/anxiety and LHPA activity are affected by isolation rearing (see Sanchez et al., 2001). Isolate-reared animals exhibit increased intensity of neurofilament protein immunoreactivity in the hippocampus (Siegel et al., 1993), as well as increased density of CRF1 receptors in the prefrontal cortex and down-regulation of CRF2 receptors in the amygdala (Sanchez et al., 1999).

Allowing surrogate-reared infants daily peer experience supports reasonably normal social development (Suomi & Harlow, 1972). LHPA effects, however, are variable (Champoux, Coe, Schanberg, Kuhn, & Suomi, 1989; Clarke, 1993; Shannon, Champoux, & Suomi, 1998). Similar to repeatedly separated infants, smaller LHPA responses to brief periods of social isolation have been observed (Shannon et al., 1998), along with atypically low GC levels early in the morning, near the peak of the rhythm (Boyce, Champoux, Suomi, & Gunnar, 1995). Diurnal temperature and rest-activity rhythms have also been found to be dysregulated in surrogate-reared animals (Lubach, Kittrell, & Coe, 1992). Peer-only rearing, in which infants are reared with only other infants as attachment figures, produces more markedly deviant stress responsivity and behavior than surrogate-peer rearing (Suomi, 1997). Studies of these animals indicate larger and more prolonged LHPA responses to separation, increased alcohol consumption as juveniles that correlates with separation-induced cortisol reactions, and a combination of both neophobia and heightened reactive aggression (Higley, Suomi, & Linnoila, 1992). Unfortunately, there have been no published anatomical analyses of surrogate-peer and peer-only reared animals. Consequently, we do not know whether their LHPA axis anomalies reflect changes in the LHPA system proper or in corticolimbic inputs to the LHPA system.

In addition to separations and various deprivation rearing manipulations, researchers have manipulated demands on the mother to disturb maternal behavior. For example, they have altered maternal foraging demands. When foraging demands are unpredictable (i.e., variable foraging demand or VFD paradigm), marked alterations in the social organization of female bonnet macaques have been noted (Rosenblum & Andrews, 1994). Specifically, VFD reduces the maternal responsiveness to infant signals, resulting in insecure patterns of attachment behavior and long-term effects on offspring development (Andrews & Rosenblum, 1994). As juveniles and young adults, VFD-reared animals tend to be fearful of new social situations and low in dom-

inance. They also have elevated CSF levels of CRH and monoamine abnormalities, suggesting that their early experiences sensitized the hypothalamic and/or extrahypothalamic CRH system (Coplan et al., 1996; Rosenblum et al., 1994).

Finally, monkey mothers do spontaneously abuse their infants. In rhesus, approximately 2% of infants are physically abused by mothers who were likely to have been abused themselves as infants (Maestriperi, 1999). Abusive behavior includes violent behaviors such as dragging the infant on the ground, crushing, throwing, or stepping/sitting on it. These abusive behaviors are observed most frequently in the first 3 postnatal months. In recent work, McCormack and colleagues (2003) noted significant alterations in LHPA functioning among abused infants. Specifically, compared to nonabused controls, abused infants exhibited higher basal morning levels of cortisol during the 1st postnatal month when abuse rates were the highest, but beginning in the 2nd postnatal month and continuing at least through the 6th postnatal month, their basal cortisol levels were suppressed, especially in the early morning hours. At 2 months of age, abused infants were unable to use maternal contact to buffer elevations in cortisol when mother and infant were captured together and singly caged for 30 minutes; in contrast, nonabused infants showed no increase in cortisol to these procedures. Of particular importance, disturbances in the LHPA system were also noted using pharmacological challenges. Specifically, the abused relative to the nonabused infants exhibited blunted ACTH responses to CRH, suggesting that some of their alterations in HPA function could be due to CRF receptor down-regulation at the level of the pituitary. Notably, down-regulation of ACTH to CRH was detected at both 6 and 12 months, many months after the infants were no longer highly dependent on maternal care. Similar but less dramatic effects of harsh treatment have also been noted in Goeldi's monkey infants (Dettling, Pryce, Martin, & Döbeli, 1998), where larger cortisol responses and behavioral distress to brief separations were obtained from infants whose parents engaged in more aggressive weaning behavior.

Summary of the Monkey Infant Studies

As in rodents, monkey mothers provide an external regulator of the LHPA and other stress-sensitive systems. In primates, separation protest (crying and searching) does not appear to be associated with LHPA activation, but defensive behaviors do, perhaps coordinated by extrahypothalamic CRH. The separation context influences the magnitude of the LHPA response. When the infant is nurtured by other

conspecifics in the mother's absence, small GC responses are obtained that resolve quickly. When the separation environment is more threatening, high GC responses are produced that may not habituate over trials. The long-term impact of the various separation and rearing environment paradigms that have been studied in monkeys are difficult to summarize. *Overall, however, as in the rodent research, the clearest impacts on infant behavior and stress neurobiology appear to arise in those paradigms that produce disturbances in mother-infant interaction or, in the case of peer-only rearing, in the supportiveness of the infant's attachment figures.* Thus, as in the rodent research, the behavior of the infant's caregivers may be the most important factor in determining the long-term impact of early adverse experiences on the development of the LHPA system. Furthermore, unlike in the rodent, more of the effects of postnatal adversity in monkeys appear to be evident on limbic circuits impacting activity of the HPA axis than on the HPA axis proper. This is consistent with the greater maturity of the HPA axis at birth in primates than in rodents.

Human Studies

In this section, we cover studies of caregiving and LHPA activity in human infants and children. These studies have been conducted through two major theoretical lenses. First, as in the nonhuman primate research, concepts and assumptions of attachment theory have guided much of the work. Second, in work on childhood maltreatment, research on adult Posttraumatic Stress Disorder (PTSD) has shaped the questions asked as well as interpretation of the findings. We first examine LHPA associations with variations in caregiving in the normative or nonabusive range and then consider LHPA studies of maltreated children.

Normative Variations in Caregiving

Consistent with attachment theory, in human infants insensitive, intrusive maternal care is associated with heightened GC activity. Insensitive or intrusive caregiving has been associated with GC increases during mother-infant play bouts (Spangler, Schieche, Ilg, Maier, & Ackermann, 1994), higher pre-session GC levels during well-child health checkups (Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996), and larger GC responses to strange and potentially threatening events (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996). In these studies, the sensitivity rather than the amount of maternal behavior seems to be the critical factor. Thus, mothers who engaged in both more and more varied, but not necessarily more sensitive, soothing activities have not been found to have infants who

exhibited smaller GC response to an inoculation stressor (Lewis & Ramsay, 1999). Similarly, mothers who engaged in more, but not more sensitive, interactions with fearful toddlers did not reduce their toddlers' GC responses to potentially threatening events (Nachmias et al., 1996).

Maternal sensitivity associated with reduced GC responses has also been shown to predict whether the mother-infant relationship would be classified as secure based on Ainsworth and Wittag's Strange Situation assessment (Gunnar, Brodersen, Nachmias, et al., 1996; Nachmias et al., 1996). When cortisol is not sampled too early following the stressor to detect the effect (e.g., Gunnar, Mangelsdorf, Larson, & Hertsgaard, 1989), the evidence fairly consistently supports the hypothesis that by the end of the 1st year, attachment security provides a powerful stress buffer in humans. There is evidence for this conclusion using stressors ranging from the Strange Situation (Spangler & Grossmann, 1993; Spangler & Schieche, 1998), to novel, arousing stimuli (Nachmias et al., 1996), to inoculations (Gunnar, Brodersen, Krueger, et al., 1996). However, as yet there is no evidence that a history of secure attachment reduces infant or toddler GC reactivity when the attachment figure is not available or when separations last more than a few minutes (see Ahnert et al., 2004). Secure attachment may foster better stress regulation, but this has been observed only in the presence of the attachment figure during the infant and toddler periods.

The hypothesis that sensitive and responsive caregiving is critical in regulating stress hormones in young children is also supported by research on nonparental caregivers. In a study in which 9-month-olds were separated from their mother for 30 minutes, infants who were randomly assigned to a sensitive and supportive babysitter condition did not produce elevations in cortisol, but those who were assigned to an unresponsive and inattentive babysitter condition did (Gunnar, Larson, Hertsgaard, Harris, & Brodersen, 1992). In a study of home-based child care, preschoolers produced increases in cortisol over the child care day if their care providers were less attentive and provided less supportive stimulation (Dettling et al., 2000).

Given evidence that unresponsive, insensitive, and/or intrusive care fails to provide an adequate stress buffer, it is not surprising that maternal depression has been associated with higher GC levels in young children. Depressed mothers are often more insensitive, erratically responsive, and/or intrusive with their children (Dawson & Ashman, 2000). Dawson and Ashman reported that right frontal EEG asymmetry in toddlers of depressed mothers was largely mediated by these aspects of maternal care. Furthermore, they found that at 3 years of age, morning GC

levels could be predicted by how clinically depressed the mother had been during the child's 1st year of life. At 7 years, these children's laboratory pretest GC levels were higher if their mother had been clinically depressed during their first 2 years (Ashman et al., 2002). Similarly, adolescents whose mother had been depressed in their 1st postnatal years were more likely to produce one or more days of elevated cortisol in the early morning, a pattern predictive of depression in previous work (Halligan et al., 2004). Furthermore, Halligan and colleagues found this effect of early maternal depression while controlling for the total number of months the mother had been depressed during the child's life and the mother's current depression status. These findings are important for two reasons. First, they suggest that higher GC levels in offspring of depressed mothers are not due merely to shared genetics. Second, they support the possibility that insensitive, unresponsive care in the early years of the child's life may shape LHPA activity.

This latter point is one implication of another study that also examined maternal depression. Essex and colleagues (2002) found that home GC levels in 4.5-year-old children were higher if the mother scored high on depressive symptoms both during the prior year and during the children's infancy. Mothers with high depression symptoms only when their children were 4 or only during infancy did not have children with higher GC levels than mothers who never had high symptom counts. Unfortunately, the researchers did not examine whether the effects of maternal depressive symptoms were mediated by intrusive, unresponsive, or insensitive treatment of the child. Furthermore, these data do not allow us to untangle the impact of chronic maternal depression from organizational effects of early maternal care that then heightens vulnerability to stressors later in the child's life.

Unfortunately, few of the studies of postnatal maternal behavior permit us to rule out prenatal influences on the development of the child's LHPA system. This is a serious shortcoming as there is increasing evidence of fetal programming of the stress neuraxis. Several recent studies suggest that exposure to elevated levels of CRH and/or cortisol prenatally may influence the behavioral and physiological reactivity of the child, at least shortly after birth (see Wadhwa, Sandman, & Garite, 2001). For example, depressed mothers tend to produce higher urinary cortisol levels around midpregnancy than do nondepressed mothers, and these levels predict the newborn's urinary cortisol levels (Diego et al., 2004). Of particular importance, it was prenatal, not concurrent postnatal, maternal cortisol values that were predictive of infant cortisol activity. We do not know how long such effects persist.

Finally, as in so many other areas, we have very little evidence that maternal depression and associated insensitive, intrusive care increase cortisol *reactivity*. In all of the studies described, maternal depression was either associated with home baseline GC or laboratory pretest GC levels. In the one study describing GC responses to a stressor, Ashman and colleagues (2002) did not find effects of depression on the GC stress response, even though associations with pretest GC levels were obtained. They did, however, find an interaction between maternal depression during the child's infancy and the child's current internalizing problems. Children with internalizing problems who had been cared for by a mother who was clinically depressed during their first 2 years had the largest GC responses to the stressor. As we will see, activity of the LHPA axis in a number of studies of maltreated children also is a function of the interaction between the individual's history of care and his or her current mental health status.

Maltreatment

Because most maltreatment occurs at the hands of parents or guardians, childhood maltreatment typically represents a profound failure of the caregiving system (Cicchetti & Rogosch, 2001a). It is also associated with host of pathological outcomes, including both affective (anxiety, depression) and disruptive behavior disorders (for review, see Pine, & Cohen, 2002). Recently, there has been increased interest in identifying the various neurobiological mechanisms through which maltreatment produces its deleterious effects (e.g., Bremner & Vermetten, 2001; Cicchetti & Tucker, 1994; J. Kaufman & Charney, 2001; Teicher, Andersen, Polcarri, Anderson, & Navalta, 2002). Most of this work has started with the assumption that maltreatment is stressful and/or traumatic and that it produces its effects, at least in part, through episodic or chronic stress. No investigator expects the effects of maltreatment to be mediated by any one neurobiological system, but most include GCs and CRH in their models. This means that there have been a relatively large number of studies of the LHPA system in relation to childhood maltreatment (see recent reviews by Bremner & Vermetten, 2001; Glaser, 2000; Heim, Ehlert, Hanker, & Hellhammer, 1998; J. Kaufman & Charney, 2001).

Childhood maltreatment, however, is a multifaceted phenomena (Glaser, 2000). It differs in type (physical, sexual, emotional, neglectful), severity, and duration, and often several types are inflicted on the same child, sometimes at different points in his or her development (Barnett, Manly, & Cicchetti, 1993). Furthermore, it often occurs in the context of family conflict, parental psycho-

pathology, economic adversity, and other factors that may also impact the child's developing stress system. As is the case for other stressors, the impact of child maltreatment on the neurobiology of stress and emotion likely depends on the age of the child, the child's gender, his or her pre-morbid functioning, and genetic factors. Finally, its effects on the developing stress system will depend on the individual's age when these effects are assessed, current life stressors, social support, mental health status, time since maltreatment, and the measure(s) chosen for assessment. Given all of these factors, it is no surprise that the literature on maltreatment and stress neurobiology includes contradictory findings.

As noted earlier, much of the research on childhood maltreatment has been generated from a trauma framework. As such, many of the questions have been derived from adult work on PTSD. In adults, PTSD in response to traumas experienced in adulthood has been sometimes (Yehuda, 2000), but not always (Bremner et al., 2003), associated with low basal GCs (particularly late in the day), prolonged GC suppression to DEX, increased GR as measured on lymphocytes, and possibly heightened negative feedback regulation of the axis. One central question in this literature is whether these LHPA abnormalities pre-date rather than follow from the trauma (see Yehuda, 2000). Childhood maltreatment is one of the risk factors for developing PTSD in response to a traumatic event experienced in adulthood. Thus, researchers have been interested in whether adults who were maltreated as children exhibit prolonged suppression of the LHPA axis in response to a low dose of DEX regardless of their current PTSD status. If so, this might indicate that early maltreatment produces LHPA alterations that serve as a risk factor for the development of PTSD to traumas encountered in adulthood. In one small study, adult women who had been sexually abused as children were given a low-dose DEX test (Stein, Yehuda, Koverola, & Hanna, 1987). Compared to controls, the maltreated women did show prolonged cortisol suppression, regardless of their current PTSD status. We do not know whether this would also be true of men or of individuals who experienced other forms of childhood maltreatment.

Other studies of adults maltreated as children provide evidence of hypofunctioning at the adrenal but not necessarily at other levels of the LHPA system. These results were obtained in individuals without current psychiatric diagnoses. Using pharmacological probes, Heim, Newport, Bonsall, Miller, and Nemeroff (2001) found elevated ACTH production in response to CRH in women who had been abused prior to puberty. At the level of the adrenal,

however, they obtained evidence of relative adrenal insufficiency. In response to both CRH and ACTH challenge tests, these women showed blunted GC responses relative to control women who had not experienced childhood abuse. Similarly, when a processive stressor rather than a pharmacological probe was used, they obtained evidence of elevated ACTH responses and normal GC reactions (Heim, Newport, et al., 2000). When the data from Heim et al. were subjected to a regression analysis to examine the effects of childhood abuse after controlling for current life events and psychopathology, peak GC and ACTH responses were both found to correlate positively with childhood abuse scores (Heim & Nemeroff, 2001). Finally, several studies of adults (male and female) who experienced physical and emotional abuse as children have reported low 24-hour urinary free cortisol (UFC) production (Roy, 2002; Yehuda, Halligan, & Grossman, 2001), although interestingly, not in women who were sexually maltreated as children (Yehuda et al., 2001).

Current psychiatric diagnosis interacts with childhood abuse in studies of the LHPA axis in adults abused as children. Thus, among depressed women maltreated as children, Heim and colleagues (Heim & Nemeroff, 2001; Heim, Newport, et al., 2000) noted elevated GC as well as ACTH responses to the TSST relative to nonabused, depressed controls. Indeed, the combination of childhood abuse and adult depression accounted for 21% of the variance in LHPA responses to the TSST. However, when a pharmacologic probe of the axis was used (i.e., CRH challenge test), similar to other depressed adults, these women exhibited a blunted ACTH reaction. In contrast, women with borderline personality diagnoses who had been maltreated as children showed augmented ACTH responses to CRH relative to similarly diagnosed women without a history of childhood maltreatment (Rinne et al., 2002). There is also evidence that adults with PTSD pursuant to childhood abuse may exhibit hyper- rather than hypo-LHPA functioning to processive stressors. Bremner and colleagues (2003) recently reported markedly elevated salivary GCs during an hour-long anticipatory period in a small sample of PTSD adults (male and female) maltreated in various ways as children. For women, no GC differences from nonpsychiatric, non-maltreated controls were obtained in response to a cognitive stressor in this study, although PTSD males abused as children showed significantly higher GC reactions.

In summary, there is some evidence that childhood maltreatment is associated with low 24-hour GC production in adulthood, consistent with other work on adults with PTSD. However, there is little evidence that childhood maltreatment decreases LHPA reactivity at levels of the

axis above the adrenal. Furthermore, there is little evidence, so far, that GC and ACTH responses to processive stressors are blunted in adults who were maltreated as children. Indeed, increased ACTH and GC reactivity to such stressors has been obtained. The LHPA effects of childhood maltreatment, however, appear to be influenced by the individual's current mental health status. Maltreated, depressed patients exhibit LHPA activity characteristic of MDD adults. Specifically, they show blunted ACTH responses to CRH challenge. Adults with PTSD who are not also clinically depressed may show exaggerated LHPA responses to psychological or processive stressors, similar to other studies of LHPA reactivity in clinical anxiety-disordered subjects.

Of course, despite the work just described, there is a great deal that is not yet known about the impact of childhood maltreatment on the activity of the mature stress system. Most of the studies have included only women. Few of the studies controlled for current life stressors, social supports, and/or recent trauma experiences. Most have had small samples that did not allow researchers to examine the timing, duration, or combinations of types of abuse to which the individual was exposed in childhood. Nonetheless, even given these limitations, the studies of adults maltreated as children tend to support the hypothesis that childhood maltreatment sensitizes the LHPA system, perhaps rendering individuals more vulnerable to stressors and increasing their risk for stress-related disorders.

This research on adults maltreated in childhood should caution us against assuming that childhood maltreatment will produce evidence of heightened activity at all levels of the axis and for all individuals. Increased pituitary responsiveness to ACTH and to psychosocial stressors may exist in concert with low cortisol baselines. Responses to pharmacological probes specific for different levels of the axis may reveal patterns of response that are markedly different from, or even the opposite of, those obtained when processive stressors that involve corticolimbic circuitry are used. Given the complexity of the findings for adults, we should anticipate that the data on children, obtained while the stress system is still maturing, might be even more complex and challenging to interpret.

As in adults, whether maltreatment is associated with increased or suppressed LHPA activity in children appears to depend, at least in part, on the child's current psychiatric diagnoses and/or behavioral disposition. Internalizing problems and/or affective disorders (PTSD or depression) interact with abuse history to produce evidence of heightened reactivity of the LHPA system. In contrast, externalizing problems in the absence of concurrent anxiety

disorders appear to reduce evidence of altered LHPA activity, at least when maltreated children are compared to normal controls. As discussed subsequently, ongoing adversity in the home may also stimulate higher LHPA activity in previously maltreated children. As current adversity is often unanalyzed, this makes interpretation of many of the studies difficult.

First we consider studies of maltreated children with PTSD. Here, unlike in adults, there is evidence of elevated rather than suppressed basal cortisol levels. Thus, DeBellis, Baum, and colleagues (1999) reported that, compared to normal controls, 24-hour UFC and urinary catecholamine concentrations were elevated in children (Tanner stage < III) with chronic PTSD pursuant to early, severe, and prolonged maltreatment. UFC and urinary catecholamine levels were also correlated positively with the duration of abuse and the number and severity of PTSD symptoms. These children's UFC concentrations, however, were only marginally higher than nonabused, clinically anxious children. Some of the children from this study were part of a larger neuroimaging study that revealed smaller brain volumes and smaller corpus callosum size but not smaller hippocampal volumes in maltreated children with PTSD relative to normal controls (DeBellis, Keshavan, et al., 1999). In a very similar set of studies, Carrion and colleagues (2001, 2002) found elevated salivary GC levels over the day in maltreated, PTSD children relative to normal controls. Using the subjects from the cortisol study plus others, they also reported reduced brain volumes and corpus callosum size, lack of hippocampal volume differences, and less asymmetry of the prefrontal cortex.

There is also evidence that depression interacts with maltreatment history to produce heightened LHPA activity. Thus, in a study of 7- to 15-year-old sexually abused girls studied within 3 to 4 years of abuse reporting, DeBellis and colleagues (1994) found marginally higher 24-hour GC levels (averaged over 3 days). Consistent with adult depression, they also found blunted ACTH but not GC responses to CRH challenge. Most of the girls in the study were dysthymic, and nearly half had attempted suicide. In contrast, J. Kaufman and colleagues (1997) found that depressed, maltreated 7- to 13-year-old children exhibited larger ACTH responses to CRH than did nondepressed maltreated children. However, this was true only of the girls who were still living under conditions of ongoing economic and social adversity. Similarly, in a study of DEX suppression, adolescent girls with PTSD pursuant to early abuse showed similar suppression of the HPA axis to the low-dose DEX test compared to a trauma/no PTSD and normal control group. Only the traumatized girls who met criteria for clinical de-

pression differed, exhibiting less DEX suppression than the other girls. Finally, there are two studies of depressed, maltreated children that have used Cicchetti's day camp paradigm to collect salivary cortisol measures (Hart, Gunnar, & Cicchetti, 1996; J. Kaufman, 1991). In both of these studies, depressed, maltreated children exhibited increasing GC levels over the camp day, but this was not observed among the nondepressed maltreated children or among the comparison children. As in the J. Kaufman et al. (1997) study, many of these depressed children were living under conditions of ongoing adversity. This was also true of maltreated children with internalizing behavior disorders studied by Cicchetti and Rogosch (2001a, 2001b). These children had higher 9 A.M. and 4 P.M. salivary GC levels averaged over 5 days of summer camp than did nonabused children with clinical levels of internalizing problems.

As noted earlier, children with externalizing problems in the absence of comorbid anxiety disorders and those with aggressive, oppositional dispositions in the nonclinical range tend to exhibit low levels of LHPA activity. If maltreatment increases LHPA activity in these children, their basal cortisol following maltreatment may not appear elevated compared to nondisordered controls, but they may still be elevated relative to nonmaltreated children with externalizing problems. Indeed, Hart and colleagues (1995) found that median cortisol levels at school did not differ among maltreated preschoolers relative to age-, sex-, and economically matched controls. However, maltreated children did exhibit less day-to-day cortisol variability, especially if they were *less* socially competent, or rather, more aggressive and undercontrolled. In addition, among the maltreated children who were so out of control that they had to be gently restrained, cortisol levels on the days requiring restraint were lower than on days when the children's behavior was more appropriate. Cicchetti and Rogosch (2001b) also found that maltreated boys, but not girls, with clinical levels of externalizing problems had higher cortisol levels at summer camp relative to nonmaltreated boys with externalizing problems. For the maltreated, externalizing boys, however, cortisol levels were not elevated over levels exhibited by nondisordered, nonmaltreated controls.

Not all maltreated children exhibit these effects. Children without behavior disorders have not been shown to have elevated basal cortisol levels (see Cicchetti & Rogosch, 2001b). These children, however, may have experienced less prolonged, varied, and/or severe maltreatment (Cicchetti & Rogosch, 2001a) and/or may be less genetically vulnerable (J. Kaufman et al., 1998). And, as noted, the presence of ongoing adversity and family dysfunction

may contribute to heightened LHPA activity in maltreated children. Despite all that remains to be understood regarding maltreatment and LHPA activity during childhood, we can at least conclude that there is little evidence of hypofunctioning or lowered basal GC levels in maltreated children, unlike the results described in studies of adults who were maltreated as children.

This difference between hypercortisolism in studies of children and hypocortisolism in studies of adults has led some to argue that hypofunctioning at the level of the adrenal, at least, emerges as a function of living for a prolonged period of time with the sequelae of trauma exposure (Yehuda et al., 2001). A longitudinal study of sexually abused girls by Frank Putnam and colleagues is cited as the best evidence for a transition from hyper- to hypofunctioning. Unfortunately, as yet, most of the results of this study are available only as conference presentations. Putnam and colleagues (Frank Putnam, personal communication, June 10, 2003) collected a group of sexually abused girls (averaging 11 years of age) who were first studied within 6 months of the abuse reporting. At this point, elevated cortisol levels were reported for girls tested in the morning hours; suppressed levels were noted for a small group of girls who self-selected into an early afternoon testing slot. DeBellis and colleagues (1994), in the study described earlier, examined a small subsample of these girls several years after abuse reporting. At that time, measures of cortisol (24-hour UFC, late afternoon baseline, response to CRH) did not differ from nonmaltreated controls. Nonetheless, low baseline ACTH and blunted ACTH responses to CRH were noted. This pattern of hypopituitary ACTH and normal cortisol activity suggests that the adrenal may have been hyperresponsive to ACTH in these girls at this point in their development. That is, the adrenal was able to sustain normal GC levels despite reduced ACTH drive. Finally, at a 7-year follow-up visit, when most of the girls were in their teens, evidence of hypocortisolism was obtained. Specifically, the previously maltreated girls had *lower* plasma GC levels than controls both at the beginning of a laboratory cognitive task and in serial samples obtained over the 30-minute cognitive challenge. Thus, this study suggests a transition from hyper- to hypocortisolism with time or pubertal development. Clearly, more longitudinal work is needed to examine dynamic changes in LHPA activity pursuant to early maltreatment and family adversity.

In this respect, an ongoing study of response to the trauma of a natural disaster may provide some useful insights. Children exposed at around age 8 to the 1988 Ar-

menian earthquake have been examined at 5 and 6.5 years following the disaster (Goenjian et al., 1996, 2003). The children were recruited from two towns, one near the epicenter that experienced incredible destruction and loss of life, and one farther away that was much less devastated. Children living near the epicenter exhibited more evidence of PTSD and depression than did those farther from the epicenter. Using one sample of children studied 5 years posttrauma, the researchers reported prolonged suppression to low-dose DEX of the adrenocortical axis in the more traumatized children, along with lower early morning, but not late afternoon, basal cortisol levels. Drawing another sample from these cities, 6.5 years posttrauma lower basal ACTH, but not cortisol, levels were noted. However, in this study, no differences in ACTH or cortisol responses to a mild exercise stressor were obtained. In both cases, measures of LHPA functioning were negatively correlated with PTSD and depression scores. These children, who were in their early adolescent years when tested, tended to exhibit the suppression of LHPA axis functioning that has been more characteristic of the adult PTSD than child PTSD literature. Although this could be because they were tested many years after the trauma exposure, several of the studies described earlier (e.g., Carrion et al., 2002; DeBellis, Baum, et al., 1999) that examined younger children were also conducted after at least this many years had transpired since the *onset* of maltreatment. This would seem to leave concurrent adversity and age at assessment (childhood versus adolescence) as critical variables needing further exploration. Of course, the neurobiological sequelae of trauma due to maltreatment and trauma due to natural disaster may well be different.

Another factor that confounds our understanding of the impact of abuse on the developing LHPA system is that many maltreated children also experience significant neglect. Neglect, while it may characterize deficient or depriving care, needs to be considered separately from abuse, as it may not, by itself, be traumatic or frightening to children. Furthermore, neglect or deprivation of care is more similar to the primate deprivation rearing paradigms (i.e., isolation, surrogate-peer rearing), which, as noted, tend to be associated with few long-term effects on the LHPA system. In most studies of maltreatment, it is extremely difficult to isolate the effects of neglect from other types of abuse, as children who are physically, sexually, and/or emotionally abused are also likely to be neglected. Indeed, in a study of nearly 400 maltreated children, after careful background checks, Cicchetti and Rogosch (2001a) were able to identify only 8% of their summer camp population

as having been subject solely to neglect. Furthermore, neglect-only histories were not associated with altered GC levels among the children studied in the day camp paradigm.

Most of the work on LHPA effects of severe neglect comes from studies of institutionally reared children. Here there is evidence of marked abnormalities in diurnal GC patterns for infants and toddlers living in institutions in Russia and Eastern Europe (as reviewed in Gunnar & Vazquez, 2001). Specifically, low early morning GC levels and a general lack of diurnal variation have been found. These results mimic those reported for rhesus infants in surrogate-peer rearing paradigms (Boyce et al., 1995). It is unlikely that the lack of what has been called the short or daytime rhythm (wake-up to bedtime) is permanent, as several years after adoption, most institutionally reared children exhibit fairly normal decreases in cortisol from wake-up to bedtime (Gunnar, Morison, Chisholm, & Schuder, 2001). There is some evidence that those from the most deprived preadoption environments, however, may exhibit slightly elevated salivary GC levels at least at some times during the day (Gunnar et al., 2001). In a recent study of postinstitutionalized children adopted from around the world, slightly higher early morning GC levels were noted only for those children who also were physically stunted at adoption and/or had parents who reported that the children experienced extreme privation prior to adoption (Kertes, Madsen, & Gunnar, 2005). Given these data, it seems likely that basal GC levels may not be strongly affected by early deprivation in human children. If so, this conclusion would be consistent with much of the animal data we reviewed earlier. What has not been studied yet is whether *reactivity* of the LHPA system is altered in children pursuant to early deprivation.

CONCLUSIONS AND FUTURE DIRECTION

In the nearly 50 years since Levine (1957) published the paper in *Science* that launched this field of inquiry, we have learned a great deal about how regulation of the LHPA system in early development influences the development of stress vulnerability and resilience. In rats, monkeys, and children, it is now well established that caregivers are potent regulators of this neuroendocrine system. In primates, sensitive, responsive care from mothers and other nurturing figures buffers the system from being activated when youngsters confront strange or threatening events. In rats, maternal behaviors surrounding feeding bouts keep this

system operating in low ranges characteristic of the stress-hyporesponsive period. In rats, monkeys, and children, separation can provoke large increases in the activity of this system, especially when separation results in a reduction in nurturance from the mother and other nurturing figures and confronts the youngster with conditions that are frightening.

We are still a long way, though, from understanding how disturbances in early care may affect the development of this system. Tremendous advances have been made in understanding these processes at the molecular level in rats. In rats, we also have a fairly detailed understanding of the developmental neurobiology of this system in relation to other neural systems involved in stress reactivity and regulation. However, as we have seen, translating the rodent findings to primates and humans is not trivial. One unanswered problem is how best to map developmental periods across species. There is no agreed upon metric. The 1st week of life in the rat is often mapped to the last trimester of gestation in humans. Each month of development in monkeys is often mapped to 4 months in humans. However, this mapping is largely based on motor maturity. Clearly, a better metric would be based on the development of the specific neural systems, in this case, the components of the LHPA system and its corticolimbic regulatory pathways. However, we lack so much information about the normative developmental neurobiology of the relevant systems in the monkey and the human that any attempt at mapping the timing from rats to monkeys to humans is crude at best. And of course, in making this mapping we cannot consider all monkeys together. The developmental neurobiology of the marmoset, squirrel monkey, and rhesus will be different. Thus, even translating across monkey species is fraught with questions about developmental neurobiology that cannot yet be answered. Yet another consideration is the fact that cortical development and therefore executive function differ among rodents, monkeys, and humans. Thus, we might expect that aspects of early experience, stress, and emotion regulation that depend on the development of corticolimbic circuits will be difficult to map across species.

One solution to this problem might seem to be to abandon preclinical models. If we are interested in human development, concentrate on studies of human development. However, there are good reasons this is not the best solution. In human infants and children, we can measure the production of GCs noninvasively using salivary measures of cortisol. We can also measure DHEA, an androgenic steroid hormone that is believed to have anticortisol effects

(see, e.g., Granger & Kivlighan, 2003). However, as this review has repeatedly demonstrated, activity of the LHPA system at the level of the adrenal (cortisol and DHEA) is only part of the story. The impact of early experiences on activity of the LHPA system can be seen at higher levels of the system (e.g., pituitary), even when it is not readily apparent at the adrenal level. Currently, blood sampling is needed to assess ACTH. Unless techniques are developed that allow noninvasive assessment of ACTH in infants and children, those of us conducting developmental studies with children will be limited in what we can understand when only humans are a part of the developmental analysis.

More critical, the long history of research that was reviewed in this chapter demonstrates that many of the important impacts of early experiences are likely operating at levels above the pituitary. Recall that in rats, early experience manipulations during the SHRP appear to produce no responses at the pituitary and adrenal level. However, measures of early genes in the hypothalamus indicate that the mpPVN may be responsive to these manipulations (see review by Cirulli & Alleva, 2003). Thus, CRH may increase in the hypothalamus and likely also in extrahypothalamic regions during the period when it is difficult to elevate ACTH and GCs in the rat. CRH in rats has been shown to have effects on the developing hippocampus and likely on other neural systems involved in stress reactivity and regulation. We do not know whether this is true in human development or, if it is true, when during development these effects might be observed. However, findings such as these should make us very wary of relying only on measures of cortisol and ACTH to understand whether activity of the LHPA system may mediate the effects of early perturbations. Thus, we need the preclinical models because of the opportunity they provide to perform the highly invasive procedures that allow measures of central CRH activity and explication of the molecular processes through which the activity of stress-sensitive systems may affect brain development. However, we must be very cautious in translating these models directly to human development.

The monkey studies provide an important lesson in this regard. These studies, along with some of the recent work with rats, challenge us to understand and integrate the impact of early experiences on corticolimbic stress and emotion regulatory pathways into the neuroendocrine early experience story. They also point to the possibility that activity of the LHPA system may be significant in shaping postnatal brain development in primates, without at the same time affecting the neurobiology of the HPA system proper. It seems very likely that some of the molecular

events that permanently alter activity of the HPA system in rodents during the first 2 postnatal weeks are events, which, if they operate in primates (including humans), typically occur prior to birth. Although this still needs to be determined, it is clear that corticolimbic pathways that are involved in regulating emotional, behavioral, and physiological responses to perturbations are immature at birth in primates and that these systems exhibit very protracted postnatal development. In humans, it is likely that these systems are not fully mature until late adolescence. The molecular evidence obtained in preclinical studies of rats and mice clearly indicates that GCs are involved in regulating genes that affect the development of relevant corticolimbic pathways and their neurotransmitter systems. Thus, it is likely that postnatal experiences that affect concurrent GC activity may affect the development frontal systems underlying stress vulnerability and resilience, without at the same time affecting the neuroanatomy and physiology of the HPA system. As noted, in primates, including humans, the time when GCs might affect developing corticolimbic pathways without altering the neurobiology of the HPA system probably covers much of the postnatal developmental period.

If true, this alters the end points we need to be examining in studies of monkeys and humans. Unlike in the rat, we are probably not looking for evidence of endogenous dysregulation of the HPA system. And, if we find this evidence, as has been shown in studies of adults who were maltreated as children, it probably means that the mechanisms are not the same as those uncovered in preweaning studies of rodents. Instead, we need to be examining measures of the relevant stress- and emotion-regulating corticolimbic systems. And, for those of us interested in whether disturbances in regulation of the LHPA system in early life may have altered development of these later-maturing systems, we need to be assessing activity of the LHPA system during the time when we expect these effects may be occurring.

Here we are in relatively uncharted waters; however, as demonstrated in this review, there are a number of indicators that this approach will be fruitful. First, there are several indications that activity of the LHPA system, as measured using salivary cortisol, predicts the emergence of emotional problems even when those problems are not apparent at the time of cortisol assessment. Thus, in the work by Essex and colleagues (Essex et al., 2002; Smider et al., 2002), higher later afternoon cortisol levels when children were 4.5 years of age were not correlated with behavior problems at that time, but they predicted the emergence of

behavior problems 1 and 2 years later. Second, in adolescents at risk for depression, spiking cortisol one or more times over the course of basal assessment predicted the onset of depression within the next few months (Goodyer et al., 2000). This was the case even though studies of early-onset depression under highly controlled conditions indicate that the LHPA system functions normally in children and adolescents with MDD (Ryan, 1998). Third, studies of children reared in orphanages reveal very atypical patterns of basal cortisol production while the children are in these orphanages. However, once adopted into families, most of the children display normal patterns of diurnal cortisol activity (Kertes et al., 2005). This is true despite that fact that many of the postinstitutionalized children with typical patterns of cortisol production exhibit elevated behavioral problems. Certainly, the studies just described do not prove the point. However, they do raise the possibility that longitudinal studies tracing relationships between LHPA regulation and adverse patterns of care during periods of rapid corticolimbic development are needed, rather than focusing our attention so narrowly on dysregulation of the LHPA system as the critical end point.

The primate studies and the presumed maturity of the LHPA system early in infancy in humans should also caution us against interpreting altered patterns of GC activity in children from adverse life conditions as evidence of dysregulation of the LHPA system. Rather, it is possible that differences in GC production under basal or response conditions may reflect ongoing adversity in the child's life. Overall, we have probably paid too little attention to children's current life circumstances in assessing LHPA activity in high-risk populations. As mentioned, sleep disturbances, unpredictable bedtimes and wake-up times, family conflict, and other circumstances of children's daily lives can affect basal GC levels, diurnal patterns of GC production, and reactivity to stressors. Assessing the impact of experiences earlier in life on current activity of the LHPA system should be greatly enhanced by careful attention to such factors in the child's life at the time of assessment. Again, as demonstrated in the work by Essex and colleagues (2002), neither early nor concurrent circumstances may be associated with GC levels in children; however, when combined, the interaction may be highly predictive. Also, as demonstrated by J. Kaufman and colleagues (1997), what appears to be dysregulation of the LHPA system may on closer inspection be evidence that when children are living in highly stressful families, their system is more sensitive to stimulation.

A call to include better assessments of the stressfulness of children's current life circumstances, however, presumes that we have a good understanding of the characteristics of situations that activate the LHPA system in children of different ages. We don't. There is good evidence in infants and young children that the security of the parent-child attachment system predicts the power of the parent's presence to buffer increases in GCs to novel, arousing, or distress-eliciting events (see review by Gunnar & Donzella, 2002). Work by Flinn and England (1995) clearly suggest that significant family conflicts can provoke elevations in GCs in children that may last several days. However, we have no clear theory of the psychosocial processes that impact the activity of the LHPA system in children. The meta-analysis of laboratory stressors used in studies of adults (Dickerson & Kemeny, 2004) may provide some guidelines for developing such a theory in developmental research. Indeed, the time may be ripe for a similar meta-analytic synthesis of the research on children. Certainly, we need clear guidelines so that we can develop laboratory paradigms that actually produce elevations in GCs in children and adolescents if we are to move beyond primarily basing our research on measures of basal and/or pretest GC levels.

In addition, we need to better understand the interaction between early experiences and individual differences in predispositions to different disorders. As demonstrated in this review, there does not seem to be a sharp or qualitative difference in the association of LHPA activity for children with behavior problems and those with temperaments or emotional dispositions that place them at risk for developing these disorders. Children with anxiety disorders tend to be more stress-reactive, but those with shy or inhibited temperament also tend to exhibit higher GC activity, at least under certain conditions. Children with disruptive behavior disorders (in the absence of comorbid anxiety) tend to exhibit low GC activity. However, school-age and older children with externalizing behaviors within the normal or nonclinical range also show negative correlations between cortisol levels and externalizing behaviors. We need a better understanding of the neurobiology of these individual differences. We also need models that will help us predict the impact of adverse experiences on the developing stress system of children with these different dispositions. These models will likely include an understanding of the role of experience in gene expression (e.g., Bennett et al., 2002). With regard to studies of LHPA activity, this will likely mean understanding how GCs and CRH interact with genes regulating the activity of monoamine systems involved in anxiety and disruptive behaviors. However, as research in

developmental psychopathology has amply demonstrated, transactional models are needed to understand development, and these models need to include how individuals influence and increasingly select their environments. Thus, research on early experiences, stress neurobiology, and developmental psychopathology will likely benefit from advances in molecular genetics, particularly if studies can be conducted in which gene and environment interactions are investigated and with a focus on how individuals both influence and are influenced by their experiences over time.

As this review demonstrates, research on early experience and stress has been fruitful. Despite this, as we attempt to adequately translate the preclinical research into its appropriate implications for human development, we have our work cut out for us. Based on the human research that has already been conducted, there is ample reason to believe that there are insights to be gained by pursuing such translational research. As the work thus far indicates, however, the translation is not likely to be direct. Nonetheless, animal models are needed to help explicate the mechanisms that transduce experience into altered neurobiological development. Adequate translation and integration of early experience stress research, therefore, will require researchers to be familiar with not only the findings but also the challenges of translating preclinical studies. This forms the basis for our final argument about future directions for this research area: Much more attention is needed in training human and animal researchers in translation and integration. To move this field forward most fruitfully, researchers studying human development need to understand both the promises and pitfalls of using the early experience animal studies as the basis for predictions about human development. Similarly, researchers doing preclinical work need to go beyond suggesting that their findings have implications for human development. Somehow, the bridge between those doing human developmental and those doing animal developmental research on early experiences and stress vulnerability needs to be built so that we can make real progress in understanding how adverse early experiences increase the risk for psychopathology.

Stress is a popular topic these days. A week seldom passes without hearing or reading about stress and its deleterious effects on health. Given this negative impact of stress on human health, many types of stress management therapies have been put forward to decrease stress and thus promote health. However, there is a great paradox in the field of stress research, and it relates to the fact that the popular definition of stress is very different from the scientific definition of stress. This has left a multitude of people and experts talking about, and working on, very different aspects of the stress response.

In popular terms, stress is mainly defined as time pressure. We feel stressed when we do not have the time to perform the tasks we want to perform. This time pressure usually triggers a set of physiological reactions (see discussion) that give us the indication that we are stressed. Although this definition is certainly accurate in terms of one component of the stress response, it is important to acknowledge that in scientific terms, stress is not equivalent to time pressure. If this were true, every individual would feel stressed when pressured by time. However, we all know peo-

ple who are extremely stressed by time pressure and others who actually seek time pressure to perform adequately (so-called procrastinators). This shows that stress is a highly individual experience that does not depend on a particular event such as time pressure; rather, it depends on specific psychological determinants that trigger a stress response.

THE ALLOSTATIC LOAD MODEL

The allostatic load model proposed by McEwen and Stellar (1993) refers to the wear and tear that the body experiences due to the repeated use of adaptive responses to stress, as well as the inefficient turning on or shutting off of these responses. Allostatic load refers to the cost the body pays for this adaptation, when this adaptation needs to be maintained for long periods of time.

Stress: Historical Background

Prior to becoming part of our day-to-day conversations, the term “stress” was used by engineers to explain forces that

can put strain on a structure. For example, one could place strain on a piece of metal in such a way that it would break like glass when it reached its stress level. In 1936, Hans Selye (reproduced in Selye, 1998) borrowed the term from the field of engineering and talked about stress as being a nonspecific phenomenon representing the intersection of symptoms produced by a wide variety of noxious agents. For many years, Selye tested various conditions (e.g., fasting, extreme cold, operative injuries, and drug administration) that would produce morphological changes in the body that were representative of a stress response, such as enlargement of the adrenal gland, atrophy of the thymus, and gastric ulceration. Selye's view of the concept of stress was that the determinants of the stress response are nonspecific; that is, many unspecific conditions can put strain on the organism and lead to disease, the same way that many unspecific conditions can put strain on a piece of metal and break it like glass.

Not all researchers agreed with Selye's model, particularly with the notion that the determinants of the stress response are nonspecific. The reason for this was simple. Selye spent his entire career working on physical stressors (e.g., heat, cold, and pain), but we all know that some of the worst stressors we encounter in life are psychological in nature and are induced by our interpretation of events. For this reason, a psychologist named John Mason (1968) spent many years measuring stress hormone levels in humans subjected to various conditions that he thought would be stressful; he intended to describe the psychological characteristics that would make any condition stressful to anyone exposed to it. This work was made possible in the early 1960s due to the development of new technology that allowed scientists to measure levels of hormones that are released during reactivity to stress. The release of stress hormones is made possible through activation of a neuroendocrine axis named the hypothalamic-pituitary-adrenal (HPA) axis.

The Hypothalamic-Pituitary-Adrenal Axis

When a situation is interpreted as being stressful, it triggers the activation of the HPA axis, whereby neurons in the hypothalamus, a brain structure often termed the "master gland," releases corticotropin-releasing hormone (CRH). The release of CRH triggers the subsequent secretion and release of another hormone, adrenocorticotropin (ACTH), from the pituitary gland, also located in the brain. When ACTH is secreted by the pituitary gland, it travels in the blood and reaches the adrenal glands, which are located above the kidneys, and triggers secretion of the so-called

stress hormones. There are two main stress hormones, the glucocorticoids (corticosterone in animals and cortisol in humans) and the catecholamines (epinephrine and norepinephrine). In humans, cortisol secretion shows pronounced circadian rhythmicity, where concentrations are at their highest in the morning (the circadian peak), progressively decline from late afternoon to early nocturnal periods (the circadian trough), and show abrupt elevations after the first few hours of sleep. The acute secretion of glucocorticoids and catecholamines in response to a stressor constitutes the primary mediators in the chain of hormonal events triggered in response to stress. When these two hormones are secreted in response to stress, they act on the body to give rise to the fight-or-flight response, whereby one would, for instance, experience an increase in heart rate and blood pressure.

By summarizing the results of studies measuring the circulating levels of these hormones before and after individuals were exposed to various jobs or situations that were deemed to be stressful (e.g., air-traffic controllers and parachute jumping), Mason (1968) was able to describe three main psychological determinants that would induce a stress response in any individual exposed to them. Using this methodology, he showed that for a situation to induce a stress response, it has to be interpreted as being *novel* and/or *unpredictable*, and/or the individual must have the feeling that he or she *does not have control over the situation*. Although this work led to a general debate between Selye (1975a) and Mason, further studies confirmed that the determinants of the stress response are highly specific and, therefore, potentially predictable and measurable.

Stress, Stressor, Stress Response, Eustress, and Distress

From this short historical background, it is becoming clear that various definitions have been given to stress. In the past few years, a growing number of scientists started to feel the need to clarify these concepts to increase our understanding of the effects of stress on human health. Based on recent reviews, McEwen and Wingfield (2003) proposed a clarification of these different concepts of stress that we use in this review. Thus, we define stress as a threat, *real or implied*, to homeostasis. In this sense, stress can be absolute (a *real* threat induced by an earthquake in a town, leading to a significant stress response in every person facing this threat), or it can be relative (an *implied* threat induced by the interpretation of a situation as being novel and/or unpredictable and/or uncontrollable, for example, a public speaking task).

Absolute versus Relative Stressors

Absolute stressors serve adaptive purposes and are those events or situations that will necessarily lead to a stress response in the majority (if not the totality) of individuals when they are first confronted with it. Being in or witnessing an accident, confronting a dangerous animal, being submitted to extreme cold or heat are all examples of absolute stressors. These extreme and particular situations constitute absolute stressors in that, due to their aversive nature, a stress response *has to* be elicited for one's survival and/or well-being. In Western societies, absolute stressors are rare but are nonetheless those that elicit the greatest physiological response. Conversely, relative stressors are those events or situations that will elicit a stress response only in a certain proportion of individuals. Moreover, this response may be mild or strong. For example, having to unexpectedly deliver a speech that will be videotaped may be very stressful for one individual and not at all for another. Large interindividual variations in the stress response to psychological challenges have been frequently reported (Hellhammer, Buchtal, Gutberlet, & Kirschbaum, 1997; Kirschbaum & Hellhammer, 1989; Kirschbaum, Klauer, Filipp, & Hellhammer, 1995; Kirschbaum, Kudielka, Gaab, Schommer, & Hellhammer, 1999; Kirschbaum, Pruessner, et al., 1995; Kudielka, Buske-Kirschbaum, Hellhammer, & Kirschbaum, 2004; Kudielka, Schommer, Hellhammer, & Kirschbaum, 2004; Lupien et al., 1997; M. Pruessner, Hellhammer, Pruessner, & Lupien, 2003; Rohleder, Wolf, & Kirschbaum, 2003; Roy, Steptoe, & Kirschbaum, 1998). As discussed in section II of this chapter, these individual differences in response to relative stressors may be due to differences in past experiences, learning, or genetic or cognitive processes. However, most of the relative stressors that lead to large interindividual variations are those stressors that imply a cognitive and/or psychosocial component (Dickerson & Kemeny, 2002). It may be argued that absolute stressors are closely linked to physiological systems due to their life- or self-threatening nature. On the contrary, relative stressors, because they are milder or because they necessitate a cognitive interpretation to elicit a response, will not necessarily lead to a physiological response, and the presence or absence of a physiological response will depend on the outcome of the cognitive analysis.

Eustress versus Distress

Situations can be interpreted as being positive, leading to eustress (good stress), or as being negative, leading to distress (bad stress). The nature (eustress versus distress) of the stress response elicited by these situations relates

more to the cognitive interpretation given to the situation (as being positive or negative to the individual) than to the physical consequence of it. To date, very few studies have been performed to assess the body's different responses to eustress or distress. However, a study performed in 1989 by Berk and collaborators assessed the hormonal response to a mirthful laughter experience in 10 healthy male subjects. In this study, half of the participants viewed a 60-minute humorous video and the other half did not. Measures of cortisol, 3,4-dihydrophenylacetic acid (dopac, the major serum neuronal catabolite of the neurotransmitter dopamine), epinephrine, and norepinephrine were assessed before and after exposure to the experimental or control conditions. The results showed that cortisol and dopac in the experimental group decreased more rapidly from baseline than in the control group, whereas epinephrine levels in the experimental group were significantly lower than in the control group at all time points. Although the authors stated that these biochemical changes have implications for the reversal of the neuroendocrine and classical stress hormone response, it has to be noted that the study was performed with a very small sample of participants (5 in each group), and the cortisol changes in response to the funny movie were not compared to the cortisol changes after exposure to a sad or aggressive movie. Consequently, it is not clear at this time whether feelings of eustress or distress lead to different hormonal responses in humans.

Stressor versus Stress Response

The stressor is the event itself, such as the earthquake in the case of the absolute stress or the public speaking task in the case of the relative stress. The stress response is the body's reaction to the event (Selye, 1975b, 1998) and can be measured by monitoring levels of cortisol and ACTH in blood or cortisol in saliva or urine. Activity within the sympathetic nervous system is measurable as levels of catecholamines in blood, urine, or saliva or by monitoring heart rate and blood pressure. Although the subjective experience of stress does not always correlate with the output of the physiological mediators of stress (Kirschbaum et al., 1999), the measurement of the body's physiological responses to environmental challenges (real or implied) nonetheless constitutes the primary means of connecting experience with resilience or the risk of disease.

Acute versus Chronic Stress

Activation of the stress response in the face of a threat (real or implied) is primordial for the survival of the species. This acute stress response, which has been

called the fight-or-flight response, allows the individual to mobilize the energy required to deal with threat. However, chronic exposure to these threats can have detrimental effects on the body. Although a wealth of data has been gathered on the effects of chronic stress on the body, almost no model has been offered to explain, predict, and measure the impact of chronic stress on the body. The main reason for this is the fact that no model has proposed a clear distinction between the positive impact of an acute response to stress and the negative impact of a chronic activation of the stress systems. Moreover, in many cases, a stressor is thought to refer to any situation that challenges the body's homeostasis and consequently is seen as being negative. However, in recent years, a new model has been developed to disentangle these different concepts and allow for a clearer description of the positive and negative effects of acute and chronic stress on the organism. This is the allostatic load model (McEwen & Stellar, 1993), but to understand what allostatic load is, one has to first understand the notion of allostasis and how it differs from the notion of homeostasis.

Allostasis versus Homeostasis

In 1929, Cannon introduced the term "homeostasis" to refer to the operation of coordinated physiological processes that maintain most of the steady states of the organism. Consequently, homeostasis is the stability of physiological systems that maintain life, such as pH, body temperature, glucose levels, and oxygen tension. These physiological systems are truly essential for life and are therefore maintained within an optimal range. The daily routines of animals and humans include nutritional inputs to maintain normal activities and to anticipate additional requirements (such as breeding, acclimating to environmental changes) during the day-night cycle and the seasons. These homeostatic mechanisms allow the individual to maintain physiological and behavioral stability despite fluctuating environmental conditions.

However, life is not always stable, and superimposed on these predictable events are facultative physiological and behavioral responses to unpredictable events that have the potential to be stressors. To respond to these unpredictable events, the system requires extra energy from endogenous stores of fat, glycogen, and protein. Consequently, to survive, an organism must be able to maintain such emergency responses. The capacity to maintain these emergency responses has been called "allostasis" (Sterling & Eyer, 1988), which implies the process of adaptation (McEwen & Stellar, 1993). Allostasis, mean-

ing literally "maintaining stability through change," describes the process of adaptation to challenge. It was introduced by Sterling and Eyer in 1988 to describe how the cardiovascular system adjusts to resting and active states of the body. This notion was generalized to other physiological mediators, such as the secretion of cortisol and catecholamines (McEwen, 1998a, 1998b; McEwen & Seeman, 1999; McEwen & Stellar, 1993).

Allostasis is positive and necessary to life. It is different from homeostasis in that it supports homeostasis; that is, it supports those physiological parameters essential for life, as environments and/or life history stages change. Indeed, homeostasis keeps "set-points" and various boundaries of control (such as pH), whereas allostasis allows for a modification of these set-points in order to face challenges. Consequently, homeostasis involves systems that are essential for life, and allostasis maintains these systems in balance as environment and life history stage change (McEwen & Wingfield, 2003).

For each system of the body, allostasis allows for short-term adaptive actions of the organism in response to environmental change. As presented in Table 14.1, for the cardiovascular system, one good example of allostasis is the role of catecholamines in promoting adaptation by adjusting heart rate and blood pressure to various conditions such as sleeping, waking, and physical exertion (Sterling & Eyer, 1988). For the metabolic system, one example of allostasis is the role of glucocorticoids at enhancing food intake and facilitating the replenishment of energy reserves after an environmental challenge (Beauman, 2000; Kuenzel, Beck, & Teruyama, 1999). For the brain, a good example of allostasis is the involvement of both glucocorticoids and catecholamines in promoting memory for emotionally meaningful events related to the environmental changes (Cahill, Prins, Weber, & McGaugh, 1994; Maheu, Jooper, Beaulieu, & Lupien, 2004; Maheu & Lupien, 2003; Roozendaal, 2000, 2003; Roozendaal, Hahn, Nathan, de Quervain, & McGaugh, 2004; van Stegeren, Everaerd, Cahill, McGaugh, & Gooren, 1998). For the immune system, an example of allostasis is the role of glucocorticoids and catecholamines in promoting trafficking of immune cells to organs and tissues where they are needed to fight an infection or other challenges (Dhabhar & McEwen, 1999). All these body responses go above homeostatic functions and serve to maintain the stability of the various systems of the body in response to environmental challenges. It is because allostasis allows for a change in the set-points of these various physiological systems that homeostasis is kept, and the body can respond adequately to environmental changes.

TABLE 14.1 Examples of Allostasis and Allostatic Load Processes, along with the Primary Stress Mediators Involved, for the Cardiovascular, Metabolic, Immune, and Brain Systems

System	Primary Stress Mediator Involved	Allostasis	Allostatic Load
Cardiovascular	Catecholamines	Act by promoting adaptation by adjusting heart rate (HR) and blood pressure (BP) to sleeping, waking, and physical exertion.	Repeated surges of BP accelerates atherosclerosis and synergizes with metabolic hormones to produce Type II diabetes.
Metabolic	Glucocorticoids	Enhance food intake and facilitate replenishment of energy reserves.	Repeated HPA activity leads to insulin resistance, accelerating toward progression of Type II diabetes, including abdominal obesity, atherosclerosis, and hypertension.
Immune	Glucocorticoids and Catecholamines	Promote trafficking (movement) of immune cells to organs and tissues where they are needed to fight infections or other challenges and modulate the expression of the hormones of the immune system, i.e., the cytokines and the chemokines.	Chronic overactivity of these mediators leads to immunosuppressive effects.
Brain	Glucocorticoids and Catecholamines	Promote retention of memories for emotionally charged events, both positive and negative.	Overactivity of these mediators lead to cognitive dysfunction, reduces neuronal excitability, induces neuronal atrophy, and in extreme cases, causes death of brain cells.

Allostatic Load: When Things Turn Bad

In 1993, McEwen and Stellar proposed the term “allostatic load” to refer to the wear and tear that the body experiences due to the repeated use of allostatic responses as well as the inefficient turning on or shutting off of these responses. Allostatic load refers to the cost the body pays for this adaptation, when this adaptation needs to be maintained for long periods of time. From the standpoint of survival and health of the individual, the most important feature of the primary stress mediators associated with allostasis is that they have protective effects in the short run. However, they can have damaging effects at longer time intervals if there are many adverse life events or if the secretion of hormones is dysregulated due to sustained stress responses. When this happens, it leads to allostatic load. As presented in Figure 14.1, McEwen and Stellar’s model describes the operating factors and the general sequence of events that occurs under conditions of acute and chronic stress (for reviews of the concept, see McEwen, 1998a, 1998b; McEwen & Seeman, 1999; McEwen & Stellar, 1993; McEwen & Wingfield, 2003; Seeman, McEwen, Rowe, & Singer, 2001). The model comprises a behavioral side, on which the individual interprets and reacts to a challenge, and a biological side, on which the body reacts to the perceived stress. The model thus comprises both a top-down processing side (interpretation of a situation as being stressful, leading to activation of the various stress systems) and a bottom-up side (the effects of the

acute and/or prolonged activation of these systems on the body and the brain).

Top-Down Processing and Allostasis

The first factor in McEwen and Stellar’s (1993) model is the reaction of the individual to physical and psychological stimuli. As presented in Figure 14.1, this reaction is in part determined by the social context and the social status of the individual. Second, the stimulus will have an effect on the individual’s information-processing system (the “processor”). The response of the processor will be determined by genetic makeup, stage of biological development, gender, past learning, and social history. If the stimulus is perceived as a threat and the source of the threat is unknown, the individual will become highly vigilant and try to determine the real nature (threat versus nonthreat) of the stimulus. If the stimulus is perceived as a threat and its source is known, the individual will try to find a coping response to the threat. If no response is available, helplessness or hopelessness may appear, with its altered physiologic responses. If a response is available, the outcome of it will depend on the cost of that response. If a low-cost response is appropriate, no stress response will be initiated. If a high-cost response is needed, it may necessitate the appearance of aggression or sensation-seeking or risk-taking behaviors. However, the available response can also be thwarted, which will eventually lead to displaced frustration or aggression. So, perceptions of threat and choice of response are central aspects of the assessment

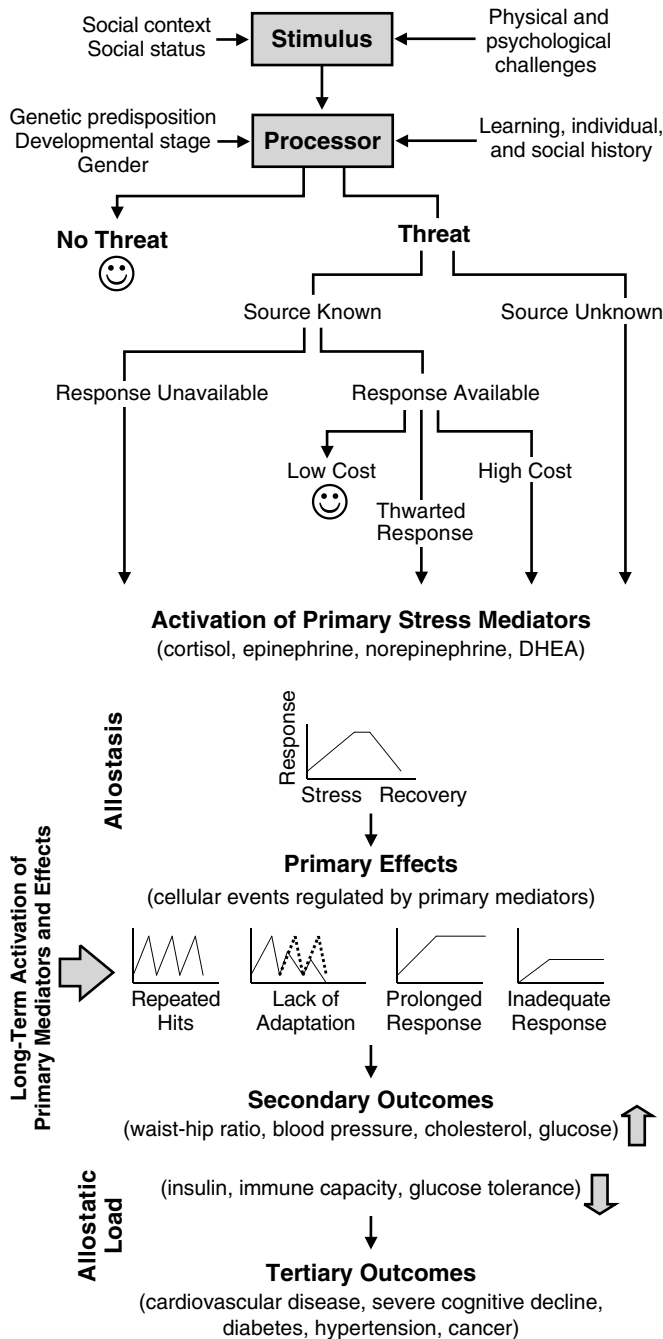

Figure 14.1 Schematic representation of the Allostatic Load model.

of risk and making choices leading to health-damaging or health-promoting behaviors.

Bottom-Up Effects and Allostatic Load

When a given situation is perceived as stressful or threatening, there will be activation of the primary stress mediators (glucocorticoids, catecholamines, dehydroepiandrosterone [DHEA]; a complete description of these mediators follows),

which will help trigger a stress response allowing the individual to deal with the threat. What is important to understand here is that the same mediators (glucocorticoids and catecholamines) that are protective and adaptive in the short run can have extremely damaging consequences if they are overproduced and/or are dysregulated for a longer period of time (McEwen, 1998a), leading to biphasic actions of the primary stress mediators.

The long-term cost to the body from allostatic load may be subdivided into at least four subtypes (McEwen, 1998a), as summarized in Figure 14.1. The first type is simply too much stress in the form of repeated, novel events that cause repeated elevations of stress mediators. For example, the amount and frequency of economic hardship predicts decline of physical and mental functioning as well as mortality (Adler et al., 1994). A second type of allostatic load involves a failure to habituate or adapt to the multiple occurrences of the same stressor. This leads to the overexposure to stress mediators because the body fails to dampen or eliminate the hormonal stress response to a repeated event. For example, when confronted with repeated public speaking challenges, most individuals habituated their cortisol response, but a few individuals continued to show cortisol response (Kirschbaum, Prussner, et al., 1995). A third type of allostatic load involves the failure to shut off either the hormonal stress response or the normal trough of the diurnal cortisol pattern. Examples of this include blood pressure elevations in work-related stress (Gerin, Litt, Deich, & Pickering, 1996; Kunz-Ebrecht, Kirschbaum, & Steptoe, 2004; Lundberg, 1996; Ming et al., 2004; Pickering, 1996a, 1996b; Pickering et al., 1996; Schwartz, Pickering, & Landsbergis, 1996; Steptoe, Siegrist, Kirschbaum, & Marmot, 2004; Steptoe & Willemsen, 2004), sleep deprivation leading to elevated evening cortisol and hyperglycemia within 5 days (Leproult, Copinschi, Buxton, & Van Cauter, 1997; Van Cauter, Polonsky, & Scheen, 1997), and depressive illness leading to chronically elevated cortisol and loss of bone mineral mass (Coelho, Silva, Maia, Prata, & Barros, 1999; Michelson et al., 1996; Robbins, Hirsch, Whitmer, Cauley, & Harris, 2001; Wong et al., 2005). The fourth type of allostatic load involves an inadequate hormonal stress response which allows other systems, such as the inflammatory cytokines, to become overactive (Chrousos & Elenkov, 2000; Elenkov, Chrousos, & Wilder, 2000). The Lewis rat is an example of an animal strain in which increased susceptibility to inflammatory and autoimmune disturbances is related to inadequate levels of cortisol (for a review, see Fournie et al., 2001). Next, we give an example of allostasis turning into allostatic load for the primary stress mediator glucocorticoids.

Glucocorticoids and Allostatic Load: An Example.

The traditional role of glucocorticoids is to promote conversion of protein and lipids to usable carbohydrates. In the short run, this is a positive aspect of this stress mediator as glucocorticoids will serve to replenish energy reserves after a period of activity such as running away from a house on fire. The same glucocorticoid will also act on the brain during this period to increase appetite for food (to replenish energy reserves) and to increase locomotor activity and food-seeking behavior (to increase energy expenditures; Leibowitz & Hoebel, 1997; Tang, Akabayashi, Manitiu, & Leibowitz, 1997). These effects of glucocorticoids are very beneficial when we have to run as fast as we can from a house on fire and when we have to replenish our energy after this intense running to maintain our daily activities. However, these effects can be detrimental when the stress response is triggered chronically by an absolute (e.g., always having to run away from a predator) or relative (e.g., a low sense of control at work) stressor.

There is an important point to make with regard to the impact of relative stressors on allostasis and allostatic load. The primary stress mediator (here, glucocorticoids) does not distinguish between a real (a house on fire) and an implied (low sense of control) threat; consequently, its activation will occur at each occurrence of the stressor (real or implied), leading to long-term secretion of glucocorticoids. Moreover, the action of glucocorticoids will be the same, that is, action on the brain to increase appetite for food (replenishment of energy reserves) and increase locomotor activity (energy expenditures). Given that, in the case of a relative stressor, the stress response has been triggered by a psychological situation rather than a real threat to survival (absolute stressor), the energy expenditure is less, but the glucocorticoids have been secreted at the same levels, activating the brain in the same way to increase food intake, with a preference for carbohydrates. Given that in Western societies, food is easily available and does not necessitate a lot of food-seeking behaviors, the energy expenditure resulting from food-seeking behavior is low. In the long run, inactivity and lack of energy expenditure, along with increased secretion of glucocorticoids, creates a situation where chronically elevated glucocorticoids can impede the action of insulin to promote glucose uptake. One of the results of this interaction is that insulin levels increase and, together, high insulin and glucocorticoids concentrations promote the deposition of body fat. This combination of hormones will also promote the formation of atherosclerotic plaques in coronary arteries, increasing the risk for coronary diseases (Brindley & Rolland, 1989).

It is when a dysregulation of other hormones occurs in response to the long-term secretion of the primary stress mediators that allostatic load appears. Other examples of allostatic load are depicted in Table 14.1 for the cardiovascular, metabolic, immune, and brain systems.

When Top-Down Processing Meets Bottom-Up Effects

As we have summarized above, once a situation has been interpreted as being threatening, a stress response will be activated, which might lead to allostatic load. What is interesting to take into account in this context is that some of the hormones secreted during the stress response will access the brain and will modify the way that further upcoming information is processed.

Allostatic Load and the Brain. As we noted earlier, one of the most important parts of the allostatic load model is the cognitive processor, which acts by deciding whether a situation constitutes a threat or not. Once this processing has been done, there will be activation (threat) or not (non-threat) of the primary stress mediators.

It is important to note here that these primary mediators (particularly glucocorticoids and catecholamines) have been shown to have important effects on the brain, leading to changes in cognitive processing. Here again, a process of allostasis and allostatic load has been observed with regard to the effects of the primary stress mediators on the brain.

Allostatic Effects on the Brain. Given the lipophilic properties of glucocorticoids, these adrenal hormones can easily cross the blood-brain barrier and enter the brain, where they can influence brain function and behavior by way of binding to different receptor types. Three of the most important brain areas containing glucocorticoid receptors are the hippocampus, amygdala, and frontal lobes, which are brain structures known to be involved in learning and memory (for reviews, see Lupien & Lepage, 2001; Lupien & McEwen, 1997). Although epinephrine does not readily access the brain due to absence of lipophilic properties, it can still act on the brain through its action on the sensory vagus outside of the blood-brain barrier, with information transmitted into the brain via the nucleus of the solitary tract (for a review, see Roozendaal, 2000). The most important brain area containing adrenergic receptors is the amygdala, which has been shown to play an important role in fear processing (for a recent review, see LeDoux, 2003) and memory for emotionally relevant information (for a recent review, see McGaugh, 2000).

Because of their actions on brain structures known to be involved in fear detection and memory for emotionally relevant information, the stress mediators enhance the formation of the so-called flashbulb memories of events associated with strong emotions, including fear but also positive emotions. This process involves the amygdala, and the pathway for encoding these memories involves the interaction between neurotransmitters in the amygdala and in related brain areas such as the hippocampus along with circulating stress hormones of the adrenal cortex and adrenal medulla (McGaugh, 2000; Roozendaal, Hahn, et al., 2004; Roozendaal, McReynolds, & McGaugh, 2004; van Stegeren et al., 1998). The importance of these stress mediators on memory for emotionally relevant information has been recently confirmed by studies in which blockade of either glucocorticoid (Maheu et al., 2004) or norepinephrine (Cahill et al., 1994) activity impaired the recall of emotionally relevant information. Consequently, secretion of these primary stress mediators is necessary for the adequate encoding of emotionally relevant information. This enhancement of memory for stimuli inducing stressful and/or emotional responses may be essential for a species' survival.

At the same time as the brain encodes information and controls the behavioral responses, it is also changed structurally and chemically by those experiences. Although for a long time it was thought that the brain of adult mammals does not generate new nerve cells, more recent evidence showed that neurons are born in the adult mammalian brain (Altman & Das, 1965). Interestingly, in the adult brain, the generation of new neurons (called neurogenesis) occurs in two regions. The first region is the subventricular zone in the wall of the lateral ventricle, where new interneurons are generated for the olfactory bulb; the second region is the subgranular zone of the dentate gyrus of the hippocampus, which gives rise to the granule cells. Moreover, recent evidence shows that adult neurogenesis in the dentate gyrus of the hippocampus is a feature of all mammalian species, occurring in rats, mice, tree shrews, marmosets, macaques, and humans (H. A. Cameron, Woolley, McEwen, & Gould, 1993; Eriksson et al., 1998; Gould, McEwen, Tanapat, Galea, & Fuchs, 1997; Gould et al., 1999; Gould, Tanapat, McEwen, Flugge, & Fuchs, 1998; Kempermann, Kuhn, & Gage, 1997). Although the functional significance of hippocampal neurogenesis has been questioned in the past, a study published in the March 2001 issue of *Nature* reported that neurogenesis in the adult is involved in the formation of trace memories, suggesting that the new neurons actually contribute to the function of the adult brain (Shors et al., 2001).

Gould and collaborators (1999) reported that training on a task that requires the hippocampal formation results in an increase in the number of adult-generated granule cells. Of particular importance, these authors showed that in untrained adult laboratory animals, the majority of generated cells degenerate within 2 weeks of production, whereas training on hippocampal-dependent tasks rescued a significant proportion of these cells. In line with experiments showing experience-dependent changes in hippocampal volumes, studies performed in adult neurogenesis show that learning can enhance the number of granule neurons. Also, comparative studies of different species show that hippocampal volume is increased in mammalian and avian species that depend critically on spatial memory for survival. Examples of such critical memory skills involve home-range navigation, migration, brood parasitism, and memory-based cache recovery in birds that hide food (Suzuki & Clayton, 2000). This association between performance of spatial tasks and hippocampal size could be explained in terms of the impact of environmental demands on hippocampal volume, rather than the converse. For example, Clayton and collaborators (Clayton & Krebs, 1994; Gerlai & Clayton, 1999) reported that the hippocampus of titmice and chickadees increases in volume in association with the experience of storing and recovering food caches. This result shows that in animals, there can be an experience-dependent hippocampal growth that occurs at a relatively late stage in development. Similar results of experience-based changes in hippocampal volumes were recently reported by Maguire and collaborators (2000) in humans. These authors tested the hypothesis that the ability of London taxi cab drivers to navigate to a specific destination correlates with hippocampal volume. They showed that compared to age-matched controls, the taxi drivers had larger posterior hippocampi. Although these results surely do not confirm that the experience of driving a taxi in the complex streets of London has a significant effect on hippocampal volumes, they nonetheless raise the intriguing possibility of hippocampal plasticity in response to environmental demands.

Allostatic Load Effects on the Brain. Although short-term responses of the brain to novel and potentially threatening situations may be adaptive and result in new learning and acquired behavioral strategies for coping, as may be the case for certain types of fear-related memories, repeated stress can cause both cognitive impairments and structural changes in the hippocampus. Each of these processes may be occurring somewhat independently of

each other and contribute in various degrees to different pathophysiological situations involving traumatic stress, depression, or aging.

The cognitive effects of long-term elevations of glucocorticoids in human populations have been studied in disorders affecting glucocorticoid levels and using exogenous administration of the synthetic compound to healthy subjects (for a review, see Lupien & Lepage, 2001). Mental disturbances mimicking mild dementia (such as decrements in simple and complex attentional tasks, verbal and visual memory, encoding, storage, and retrieval) have been described in depressed patients with hypercortisolism (R. M. Cohen, Weingartner, Smallberg, Pickar, & Murphy, 1982; Rubinow, Post, Savard, & Gold, 1984; Vythilingam et al., 2004; Weingartner, Cohen, Murphy, Martello, & Gerdt, 1981; Wolkowitz et al., 1988; Wolkowitz et al., 1990) and in steroid psychosis following glucocorticoid treatment (Hall, Popkin, Stickney, & Gardner, 1979; Ling, Perry, & Tsuang, 1981; Varney, Alexander, & MacIndoe, 1984; Wolkowitz, Reus, Canick, Levin, & Lupien, 1997). Similar cognitive deficits are also reported in patients suffering from Cushing's disease (O. G. Cameron, Starkman, & Schteingart, 1995; Starkman, Gebarski, Berent, & Schteingart, 1992; Starkman, Giordani, Berent, Schork, & Schteingart, 2001; Starkman et al., 1999; Starkman, Giordani, Gebarski, & Schteingart, 2003). During human aging, a significant proportion of elderly individuals present an endogenous increase of glucocorticoid levels (Lupien et al., 1996), and this increase has been related to impaired memory performance (Lupien et al., 1994).

Although an allostatic process has been shown to lead to positive structural changes of the hippocampus, it is important to note that an allostatic load process has also been shown to have significant detrimental effects on this brain structure. For example, treatment of adult rats with corticosterone decreases the proliferation of granule cell precursors (H. A. Cameron & Gould, 1994), and removal of adrenal steroids stimulated the generation of new granule neurons (H. A. Cameron & McKay, 1999). Given the suppressive actions of glucocorticoids on hippocampal neurogenesis, stressful experiences have been suggested to inhibit cell proliferation in adulthood, a hypothesis that has been demonstrated. Long-term stressful experience decreases the number of adult-generated neurons in the dentate gyrus in various species, including the rat (Heale, Vanderwolf, & Kavaliers, 1994; Sgoifo, de Boer, Haller, & Koolhaas, 1996), tree shrew (Gould et al., 1997), and marmoset (Gould et al., 1998). In a similar vein, repeated stress produces prolonged suppression of cell proliferation

in the dentate gyrus of the adult tree shrew (Fuchs, Uno, & Flugge, 1995). Stress-induced decreases in dentate gyrus cell proliferation could also contribute, in line with atrophy of the pyramidal cells of the hippocampus, to changes in hippocampal volumes observed after chronic exposure to stress.

Smaller hippocampal volumes associated with chronic elevations of glucocorticoids have also been reported in humans. Over the past 2 decades, many studies revealed the presence of smaller hippocampal volumes in various psychiatric disorders, such as depression (Krishnan et al., 1991; Sheline, 1996; Sheline, Gado, & Kraemer, 2003; Sheline, Sanghavi, Mintun, & Gado, 1999; Sheline, Wang, Gado, Csernansky, & Vannier, 1996; Vythilingam et al., 2004), Posttraumatic Stress Disorder (Bremner, 2002, 2003; Vythilingam et al., 2002), and Schizophrenia (Heckers, 2001; Nelson, Saykin, Flashman, & Riordan, 1998), all of which involve glucocorticoid-level dysregulations. Hippocampal atrophy associated with chronic exposure to high levels of glucocorticoids is also reported in patients with Cushing's disease (Starkman et al., 1992; Starkman et al., 1999) and elderly individuals (Lupien et al., 1998). A recent study of Cushing's patients revealed that surgical treatment of hypercortisolism in these patients leads to a reversal of the glucocorticoid-induced hippocampal atrophy reported to occur in this population, with an average volume increase of 3.2% and variations up to 10% in some patients (Starkman et al., 1999). This is a significant finding as it implies the possibility of functional reorganization of the hippocampus once the allostatic load process has been taken away. Reversibility and/or preventability of such atrophy is a major topic for future research, as is the implication of such treatment for cognitive function.

Chronology of the Allostatic Load Process. As we have stated in previous sections, the activation of the primary stress mediators represents an allostatic process whereby an adaptive response to an environmental threat is organized. However, after repeated exposure to various situations that lead to activation of these stress mediators (either through repetitive hits, failure to habituate, prolonged response, or inadequate response), allostatic load will develop. Consequently, there exists a chronology of hormonal and cellular events in the development of allostatic load that can allow for a measure of the level of allostatic load in any given individual. The chain of events in the allostatic load process begins with the allostatic activation of primary mediators, with the resulting primary effects. After prolonged allostatic attempts at adaptation, other

hormonal and cellular processes will become dysregulated, leading to secondary and tertiary outcomes. We summarize these next.

Primary Mediators of Allostatic Load. The primary mediators of allostatic load are those chemical messengers that are released as part of allostasis (see Table 14.2). At present, there are four primary mediators included in the assessment of allostatic load: cortisol, epinephrine, norepinephrine (the catecholamines), and DHEA. These chemical messengers are primary mediators because they have widespread influence throughout the body and are very useful (when measured correctly) at predicting a variety of secondary and tertiary outcomes.

As summarized earlier, cortisol (the most important glucocorticoid in humans) has wide-ranging effects throughout the body. Receptors for glucocorticoids are present in virtually every tissue and organ in the body and mediate effects ranging from the induction of liver enzymes involved in energy metabolism to regulating the trafficking of immune cells and cytokine production to facilitating the formation of fear-related memories.

DHEA is a functional antagonist of cortisol (May, Holmes, Rogers, & Poth, 1990; Wright, Porter, Browne, & Svec, 1992) that may also have effects via other signaling pathways (Araneo & Daynes, 1995); generally, low DHEA is considered deleterious, as is chronically high cortisol (Morales, Nolan, Nelson, & Yen, 1994). Blood level of DHEA, most of which is present in the sulfated form (DHEAS), peaks at approximately 20 years of age and declines rapidly and markedly after age 25 (Orentreich, Brind, Rizer, & Vogelmann, 1984). The accumulation of abdominal fat increases with aging, and abdominal obesity increases the risk for development of insulin resistance, diabetes, and atherosclerosis (Cefalu et al., 1995). In rats, DHEA has protective effects against both the insulin resistance induced by a high-fat diet (Hansen, Han, Nolte, Chen, & Holloszy, 1997) and the decrease in insulin responsiveness that occurs with advancing age (Han, Hansen, Chen, & Holloszy, 1998).

The catecholamines epinephrine and norepinephrine are released by the adrenal medulla and sympathetic nervous system, respectively, and produce widespread effects throughout the body, ranging from vasoconstriction and acceleration of heart rate to trafficking of immune cells to targets, as well as enhancement of fear-related memory formation (Cahill et al., 1994). Adrenergic receptors are widespread throughout the body, in blood vessels and target organs such as the liver, pancreas, and brain, which is not

TABLE 14.2 Various Stages of Allostatic Load and the Physiological and Clinical Markers Used to Assess the Degree of Allostatic Load

Stages of Allostatic Load	Physiological and Clinical Markers
Primary mediators	Glucocorticoids DHEA Adrenaline Noradrenaline <i>Cytokines</i>
Primary effects	Cellular events (enzymes, receptors, ion channels, structural proteins) that are regulated by the primary mediators as part of allostasis (not well studied).
Secondary outcomes	Reflect the cumulative outcomes of the primary effects and the outcomes of more than one primary mediator. Waist-hip ratio Blood pressure (systolic and diastolic) Heart rate Glycosylated hemoglobin HDL (High Density Lipoprotein) Total cholesterol Glucose Insulin Poor glucose tolerance <i>Nitric oxide</i> <i>Fibrinogen</i> <i>Immune delayed-type hypersensitivity</i> <i>Immunization challenge response</i> Frequency and severity of common cold Mild cognitive decline unrelated to age
Tertiary outcomes	Actual diseases or disorders that are the result of the allostatic load that are predicted from the extreme values of the secondary outcomes and of the primary mediators. Cardiovascular disease Severe cognitive decline Decreased physical capacity Cancer

Note: It is important to note that there are other primary mediators that may be included in the allostatic load model, but we have selected a subset of these for clarity. These potential additional mediators are presented in italics and are not discussed in the text. Also, it is important to underline that all these mediators operate as an interacting network and not necessarily in a linear fashion, as the table might suggest.

accessible to circulating catecholamines. However, catecholamines signal the brain through the sensory vagus and the nucleus of the solitary tract, as in learned fear.

Primary Effects of Allostatic Load. The primary effects of allostatic load have not been measured extensively, but these include cellular events, the actions of enzymes,

receptors, ion channels, and/or structural proteins that are induced genomically or phosphorylated via second messenger systems that are regulated as part of allostasis by the primary mediators (see Table 14.2).

For example, glucocorticoids regulate gene expression via several pathways, involving interactions with DNA via the glucocorticoid response elements and also via protein-protein interactions with other transcriptional regulators (Miner, Diamond, & Yamamoto, 1991). As noted earlier, DHEA antagonizes glucocorticoid actions in a number of systems. Catecholamines act via alpha and beta adrenergic receptors, and beta receptors stimulate the formation of the intracellular second messenger, cyclic AMP (cAMP), which, in turn, regulates intracellular events via phosphorylation, including transcription regulators via the CREB family of proteins (Siegel, Agranoff, Albers, Fisher, & Uhler, 1999).

In some cases, the glucocorticoid and cAMP pathways converge at the level of gene expression (e.g., see Yamada, Duong, Scott, Wang, & Granner, 1999). Therefore, it is not surprising that secondary outcomes (see later discussion) are the result of more than one primary mediator. Consequently, primary effects are organ- and tissue-specific, and secondary outcomes reflect the integrated actions of the primary effects.

Secondary Outcomes. The secondary outcomes are the integrated processes that reflect the cumulative outcomes of the primary effects in a tissue/organ-specific manner in response to the primary mediators (see Table 14.2). Consequently, they often reflect the actions of more than one primary mediator. Examples of secondary outcomes are evident in waist-hip ratio (abdominal fat deposition), blood pressure elevation, glycosylated hemoglobin, the ratio of cholesterol to HDL High Density Lipoproteins (HDL), and HDL cholesterol. These are secondary outcomes because they reflect the effects of sustained elevations in glucose and the insulin resistance that develop as a result of elevated cortisol and elevated sympathetic nervous system activity (primary mediators). Blood pressure elevation is part of the pathophysiological pathway of metabolic syndrome but is also a more primary indication of the allostatic load that can lead to accelerated atherosclerosis as well as insulin resistance. Cholesterol and HDL cholesterol are measures of metabolic imbalance in relation to obesity and atherosclerosis and also reflect the operation of the same primary mediators as well as other metabolic hormones.

Another important secondary outcome is mild cognitive decline without dementia; this secondary outcome relates to

the detrimental effects of long-term exposure to high levels of glucocorticoids and catecholamines on cognitive processing in humans (Lupien et al., 1998; Lupien et al., 1994). More recently, we have also included specific outcomes related to the damaged pathway in cardiovascular disease and risk for myocardial infarction (e.g., nitric oxide, fibrinogen). Fibrinogen, one of the blood-clotting factors, has already been used as an allostatic load measure in relation to job stress and socioeconomic status (Markowe et al., 1985). Finally, outcomes related to other systems such as the immune system have now been included. Here, integrated measures of the immune response such as delayed-type hypersensitivity (Dhabhar & McEwen, 1999) and immunization challenge (Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996) should reveal the impact of allostatic load on cellular and humoral immune function and help distinguish between the immunoenhancing effects of acute stress and immunosuppressive effects of chronic stress. Moreover, assessment of the frequency and severity of the common cold (S. Cohen et al., 1997; S. Cohen, Tyrrell, & Smith, 1991) is another indirect way of assessing immune function, and this might be considered a secondary outcome.

Tertiary Outcomes. The tertiary outcomes are the actual diseases or disorders that are the results of the allostatic load that is predicted from the extreme values of the secondary outcomes and of the primary mediators (see Table 14.2). Thus far, the tertiary outcomes that are thought to result from allostatic load are cardiovascular disease, decreased physical capacity, severe cognitive decline, and cancer.

With regard to the chronology of the allostatic load model, it is important to note that in the allostatic load formulation, the impact on health risk is thought to result not only from large and clinically significant deviations from normal operating ranges, but also from more modest dysregulations if they are present in multiple systems. McEwen and Stellar (1993) hypothesized that the cumulative impact on health risk from modest dysregulations in multiple systems can be substantial, even if they individually have minimal and insignificant health effects.

Validation of the Allostatic Load Model

Although the concept of allostatic load offers a great opportunity to explain various stress-related disorders, the model remains static as long as it has not been validated with experimental data. It thus became important to assess the predictive power of the allostatic load model in various populations.

Allostatic Load and Aging. In a first validation study, data were used from the MacArthur Successful Aging Study that pertains to levels of physiologic activity across a range of important regulatory systems, including the HPA and sympathetic nervous systems as well as the cardiovascular system and metabolic processes (Seeman et al., 1994; Seeman & Chen, 2002; Seeman, McEwen et al., 2001; Seeman, Singer, Rowe, Horwitz, & McEwen, 1997). In this study, Seeman and collaborators (Seeman, Crimmins, et al., 2004) evaluated the capacity of an allostatic load score to predict four categories of health outcomes in 1,189 men and women aged 70 to 79 followed over a period of 7 years. The measure of allostatic load used in this first validation study reflected only one of the two aspects of physiologic activity postulated to contribute to allostatic load, namely, higher, chronic, steady state levels of activity related to the diurnal variation as well as any residual activity reflecting chronic stress or failure to shut off responses to acute stressors. The parameters that were available for determining allostatic load scores included urinary cortisol, adrenaline, noradrenaline; serum DHEA; waist-hip ratio, diastolic and systolic blood pressure, glycosylated hemoglobin, serum HDL, and total cholesterol. For each of the 10 indicators of allostatic load, subjects were classified into quartiles based on the distribution of scores in the baseline cohort. Allostatic load was measured by summing the number of parameters for which the subject fell into the highest risk quartile, leading to an allostatic load score for each participant. The results showed that higher baseline allostatic load scores were associated with significantly increased risk for 2.5-year (Seeman et al., 1997) and 7-year (Karlman, Singer, McEwen, Rowe, & Seeman, 2002; Seeman, McEwen et al., 2001) mortality, as well as declines in cognitive and physical functioning, and were marginally associated with incident cardiovascular disease events. More important, although none of the 10 components of allostatic load exhibited significant associations on its own with health outcome, the summary measure of allostatic load was found to be significantly associated with these four major health outcomes. These findings were consistent with the idea that although a modest deviation in the level of activity of a single physiologic system may not be predictive of poor future health, the cumulative toll from modest alterations in several physiologic systems is a prognosis of poor health.

Allostatic Load across the Life Span. In a more recent study, Crimmins and collaborators (Crimmins, Johnston, Hayward, & Seeman, 2003) assessed age differences in allostatic load from a large nationally representative

sample in the United States. The National Health and Nutrition Examination Survey involved the collection of data over the period 1988 to 1994 in 18,000 individuals 20 years of age and older. Using the data from this study, an allostatic load index was constructed using 13 indicators of physiological dysregulation and analyzed using the quartile method of Seeman and colleagues (Seeman, McEwen, et al., 2001; Seeman et al., 1997). Results showed that allostatic load score increased with age through the 60s and then leveled off, so that individuals above 60 years of age had fairly similar levels of allostatic load. The ratios of one age group to the preceding showed that the increase in allostatic load score from one age group to the next was .4 or .5 in the first 2 decades of adulthood, and was .2 to .3 in the next decades. The change in allostatic load score after these decades (after 60 years) did not change significantly. Although these results were not linked to subsequent health outcomes, they revealed an interesting pattern of increasing allostatic load score, starting in the early decades of adulthood.

Allostatic Load and Work Conditions. Adverse work characteristics and poor social support have been associated with an increased risk for cardiovascular disease and other adverse health outcomes. To assess whether an allostatic load index could be a good predictor of work characteristics, Schnorpfeil and collaborators (2003) performed a cross-sectional study with 324 industrial workers in Germany. Psychosocial work characteristics were assessed using various validated questionnaires, and an allostatic load index was assessed using 14 physiological components of the allostatic load model; the analysis was performed using the quartile method (Seeman, McEwen et al., 2001; Seeman et al., 1997). The results revealed that older individuals, particularly men, had significantly higher allostatic load scores than younger participants or women. Of the various work characteristics evaluated, only job demands related significantly with the allostatic load score. This association persisted after controlling for smoking status and gender and after excluding participants reporting hypertension, cardiovascular disease, or diabetes. However, the authors also showed that the association between job demands and allostatic load was highly dependent on age, with little or no association in younger participants, and an increasing effect of job demands on allostatic load score in participants over 45. These results go along with the notion that allostatic load results from the cumulative impact of wear and tear that occurs throughout life and that adds up with increasing age.

Allostatic Load and Socioeconomic Status. In a more recent study, the data from the MacArthur Studies of Successful Aging were used to assess whether the socioeconomic status (SES) differences in mortality can be partially explained by differences in allostatic load (Seeman, Crimmins, et al., 2004). Results showed that the score of allostatic load explained 35.4% of the difference in mortality risk between those with higher versus those with lower SES. Of importance, it was shown that the cumulative index provided independent explanatory power over and above a measure of doctor-diagnosed disease. Here again, the summary measure (allostatic load score) accounted for more variance than individual biological parameters in predicting health outcomes, suggesting the high potential value of this multisystem view of biological pathways through which SES ultimately affects morbidity and mortality.

Allostatic Load and Social Support. Allostatic load scores have not only been associated with negative outcomes; new studies now show that the presence of social support in an individual's life is a strong predictor of low allostatic load scores later in life. The first report of a significant association between allostatic load score and social support was published by Singer and Ryff in 1999. These authors used data from the Wisconsin Longitudinal Study and searched for precursors to allostatic load via ordered categories of cumulative adversity relative to advantage over the life course. They operationalized life trajectories via economic circumstances and social relationship experiences (e.g., parent-child interactions, quality of spousal ties). The results of this study revealed a strong association between the extent of adversity early in life and the likelihood of high allostatic load later in life. More important, they showed that resilient individuals with economic disadvantage but compensating positive social relationship histories showed low prevalence of high allostatic load. In 2001, using data from the MacArthur Study of Successful Aging, Seeman and collaborators (Seeman, Lusignolo, Albert, & Berkman, 2001) reported that greater baseline emotional support in the participants of this longitudinal study was a significant predictor of better cognitive function at the 7.5-year follow-up, controlling for baseline cognitive function and known sociodemographic, behavioral, psychological, and health status predictors of cognitive aging. Finally, in a recent study using data from the Social Environment and Biomarkers of Aging Study in Taiwan, Seeman and collaborators (Seeman, Gleib, et al., 2004) examined relationships between social environment characteristics and allostatic load in two groups of older Taiwanese individuals split as a function of age (54 to 70, and

71 and older). They used the longitudinal data on levels of social integration and extent of social support as predictors of cumulative allostatic load. The results showed that in the 54 to 70 age group, the presence of a spouse in early years (6 to 8 years prior to the collection of data) was associated with lower allostatic load in men, but not women. In the older group of participants (71 years and above), it was found that ties with close friends and/or neighbors were significantly related to lower allostatic load score for both men and women. Interestingly, although significant, these relationships between social support and allostatic load were more modest than the associations reported to occur in Western societies. The authors suggested that contextual, normative influences on social experience may affect the patterns of association between features of these social worlds and the physiological substrates of health.

Conclusion

Many important points result from our analysis of the allostatic load model. First, cumulative wear and tear have effects on the body through lifelong exposure to various challenges. Second, the data obtained so far show that allostatic load tends to develop in time and increase sharply in the later decades of adult life. These data also show that environmental conditions, such as high job demands and poverty, are associated with higher allostatic load scores. However, the presence of social support, either in early life or later in life, is a strong predictor of low allostatic load. These results suggest that allostatic load is a process that could begin very early in life, and that, depending on the environmental conditions to which children are exposed, they may develop an allostatic load process very early in development.

In the next sections of this chapter, we summarize data and concepts pertaining to the potential pathways by which allostatic load can develop in children facing adversities.

EARLY ADVERSITY AND THE DEVELOPMENT OF ALLOSTATIC LOAD

Following a definition by Sandler (2001), adversity can be characterized as a condition that threatens the satisfaction of basic human needs and goals (including physical safety, self-esteem, efficacy, and social relatedness) and constrains the accomplishment of developmental tasks such as school success and positive role functioning at home. Many conditions have been related to early adversity, the most important of them being low SES, child maltreatment, and war. In the following, we discuss some data related to these

different types of early adversities. Although we are aware that each type of adversity may have very different effects on the body's response to stress, it is important to note that there have not been enough studies performed so far on this particular issue to allow us to offer a clear distinction across these different forms of adversity. Consequently, we discuss these adversities generally as conditions very early in life that threaten the satisfaction of a child's basic needs and goals (Sandler, 2001).

Many studies on adversity have looked at the effects of low SES on health and well-being. It has been found that individuals from high SES environments enjoy better health than individuals from low SES environments. Various studies have shown that blood pressure (Breier et al., 1987) increases significantly as employment grade (B. S. Dohrenwend, 1973), occupational status (Adelstein, 1980), income (Folkman, Schaefer, & Lazarus, 1979), or years of education (Adelstein, 1980) decrease. Although most of the literature has concentrated on systemic diseases, other studies have shown a significant relationship between SES and mental health. For instance, inverse associations have been reported between SES and the prevalence of Schizophrenia, Posttraumatic Stress Disorder, Major Depression, alcoholism, substance abuse, Antisocial Personality Disorder, and nonspecific distress (B. P. Dohrenwend, 2000).

With regard to developmental pathways, the exposure to adverse conditions in childhood is closely related to the development of physical and mental health problems in adulthood (Sandler, 2001). The relationship is of a cumulative nature; that is, the greater the number of adverse experiences, the more likely is development of a variety of problems later in life. For instance, Felitti et al. (1998) reported a 4- to 12-fold increased risk for alcoholism, drug abuse, depression, and suicide attempts in adults who had experienced four or more adversities in childhood.

Although the relationship between early adversity and health is well documented, the mechanisms that account for the relationship are not clearly understood (e.g., Sandler, 2001). One possible pathway that links adversity to health problems is stress (e.g., Lupien, King, Meaney, & McEwen, 2001; McLoyd, 1998). As stated earlier, adversity is a condition that threatens the satisfaction of basic human needs. The consequence of perceiving such a threat is a state of stressful arousal (e.g., Sandler, 2001). With respect to SES, it has been shown that low SES individuals are exposed to a greater amount of chronic and acute threats/stressors than high SES individuals (e.g., Bradley & Corwyn, 2002). Environmental as well as social/psychological factors contribute to the increased stress levels. With regard to environmental factors, low SES is associ-

ated with poor living conditions, overcrowding, exposure to environmental hazards, and crime (e.g., Bradley & Corwyn, 2002; Haan, Kaplan, & Syme, 1989). With regard to sociological/psychological factors, it has been shown that lower SES increases the likelihood of exposure to negative events such as social aggression, family conflict, and risk behaviors (B. S. Dohrenwend & Dohrenwend, 1970). Additionally, low SES individuals are exposed to a higher rate of change and instability in their lives such as family dissolution and household moves. This instability has been found to produce a higher level of individual distress in these individuals (Broadhead et al., 1983; B. S. Dohrenwend & Dohrenwend, 1970). Moreover, individuals who have access to psychological and material support from family, spouses, or friends during stressful events appear to be in better health compared to individuals without significant support (Broadhead et al., 1983; S. Cohen, 1988; Schwarzer & Leppin, 1989; Starfield, 1982). Individuals low on the SES hierarchy have fewer of these social and psychological resources to cope with stressful life events than individuals higher in the SES hierarchy (S. Cohen, 1988; House et al., 1994; McLeod & Kessler, 1990).

To assess whether the development of the relationship between SES and mental health is sustained, at least in part, by exposure to high levels of glucocorticoids, Lupien and collaborators (Lupien, King, Meaney, & McEwen, 2000; Lupien et al., 2001) measured morning salivary cortisol levels and cognitive function (memory, attention, language, and emotional processing) in 396 children (from 6 to 16 years of age) from low versus high SES in the Montreal area in Canada (Lupien et al., 2001). Depressive symptomatology and exposure to stressful events were also assessed in each child's mother through a semistructured phone interview. The results revealed that low SES children from 6 to 10 years old presented significantly higher salivary cortisol levels when compared to children from high SES. This difference disappeared at the time of school transition, that is, at 12 years old, and no SES differences were observed at 12, 14, and 16 years of age. The absence of SES differences in cortisol levels during high school could be due to changes in cortisol secretion in relation to social roles (importance of peers over family, youth culture, etc.; see Lupien et al., 2001), or to the fact that those teenagers from low SES who were available to perform this study were the most resilient, that is, were those teenagers who decided not to quit school. Neuropsychological data showed that although children from low and high SES do not differ with regard to memory, attentional, and linguistic functions, children from low SES (at all ages) presented a significantly higher level of negative emotional

processing (Lupien et al., 2005). Scores on the depression and stress questionnaires were significantly higher for low SES mothers, when compared to high SES mothers. More important, the authors reported a significant positive correlation between the mother's depressive symptomatology and her child's cortisol level (Lupien et al., 2000). This showed that the higher the score of the mother on the depressive scale, the higher the cortisol level of her child. Altogether, these results showed that low SES in young children is related to increased cortisol secretion and negative emotional processing. Moreover, they showed that depression in the mother is, in conjunction with low SES, a significant factor predicting high cortisol levels in children.

Other studies have reported a significant association between early adversities and/or mother's depression on a child's glucocorticoid levels. For example, numerous retrospective studies of adults and children have shown that increased reactivity of the HPA system is associated with early trauma (Cicchetti & Rogosch, 2001; Heim et al., 2000; Kaufman et al., 1997; Yehuda, Halligan, & Grossman, 2001), as well as severe deprivation (Gunnar, Morison, Chisholm, & Schuder, 2001). Moreover, studies of infants and toddlers suggest that maternal postpartum depression and behaviors, with the insecure mother-child attachments that can result from these conditions, are positively associated with children's cortisol levels (Field, 1994; Spangler & Grossmann, 1993). In a longitudinal study of children of depressed mothers, Hessl and collaborators (1998) found that postpartum depression was positively associated with children's cortisol at 3 years of age, although another study reported no effect of maternal depression on cortisol levels when the children were age 7 (Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002).

However, in another study, Essex and collaborators (Essex, Klein, Cho, & Kalin, 2002) measured salivary cortisol levels in 282 children age 4.5 years and 154 of their siblings. The authors were able to obtain maternal reports of stress when the children were ages 1, 4, and 12 months and again at 4.5 years. Finally, they assessed the child's mental health symptoms in the first grade of school. In the first cross-sectional analysis of the association between actual maternal stress and the actual child's cortisol levels, Essex and collaborators found that at 4.5 years of age, the children exposed to high levels of concurrent maternal stress presented significantly higher cortisol levels than children exposed to moderate or low levels of maternal stress. Very interestingly, they also revealed a similar association of exposure to concurrent maternal stress and cortisol levels in the siblings of these children. The analysis of the longitudinal data revealed that the children who were

exposed to high levels of concurrent actual maternal stress and who were initially exposed to high maternal stress in infancy (thus exposed to high maternal stress both in infancy and at 4.5 years of age) were the only group that had significantly higher cortisol levels. No effects of maternal stress on child's cortisol levels were observed for children exposed to maternal stress in infancy only. These results suggest that exposure to concurrent maternal stress is associated with increased cortisol levels only for children whose exposure began in infancy. The authors then addressed the potential association between child's cortisol levels and behavioral problems. Results showed that the preschoolers with high cortisol levels presented greater internalizing and externalizing symptoms when assessed 2 years later. Finally, the link reported between low SES and higher cortisol levels in children (Lupien et al., 2001) was replicated in this study.

In a more recent study, G. W. Evans and Marcynyszyn (2004) analyzed cross-sectional data from 216 third-through fifth-grade low- and middle-income children in upstate New York. The data of this study included overnight urinary neuroendocrine levels, noise levels, residential crowding (people per room), and housing quality. The authors calculated an index of cumulative environmental risk exposure based on the number of risk factors (i.e., crowding, indoor noise, and housing quality). Risk exposure for each factor was designated as greater than 1 standard deviation above the mean and given a score of 1. The other exposure levels were considered lower risk and coded as 0. The results revealed that cumulative environmental risk exposure was significantly greater for low-income children. More important, the authors showed that cumulative environmental risk was positively correlated with elevated overnight epinephrine, norepinephrine, and cortisol in the low-income sample but not in the middle-income sample. These results remained significant after controlling for income, maternal education, family structure, age, and gender.

Altogether, these results strongly suggest that early exposure to adversity (through low SES, maternal stress/depression, or maltreatment) can have potent and long-lasting effects on the secretion of glucocorticoids in children. Although these studies provide very interesting results with regard to the influence of early adversities on a child's basal cortisol levels, they do not provide an answer to a very important question about the allostatic load model: What determines the initial processing of an information as being threatening (leading to the secretion of the primary stress mediators) or nonthreatening? Indeed, as we have discussed in previous sections, various situations can be real

threats (a house on fire) or implied threats (interpretation of a situation as being novel and/or unpredictable and/or uncontrollable), and both types of stressors will lead to the activation of primary stress mediators and potentially to allostatic load. It is thus becoming extremely important to understand the mechanisms by which early adversities might shape a child’s cognitive processing and lead to a healthy or biased processing of incoming information and, consequently, to cumulative allostatic load due to repeated activation of the primary stress mediators when situations are interpreted most of the time as being stressful.

The Subjective Nature of Reality: The Human Information-Processing System

Cognitive psychology is concerned with how people perceive, learn, remember, and think about information. Since the 1960s, the human brain has often been conceptualized as an information-processing device. From studies in cognitive psychology, we have learned that what we perceive is not an exact replica of the external world. Instead, perceptual processes transform and interpret information from the external world. Additionally, our mental capacities are limited, and to further process information, we have to allocate our mental resources to certain stimuli, a process called selective attention. Stimuli we attend to enter a short-term or working memory store; from there, some of the information will eventually be transferred into long-term memory, the memory system that stores our experiences (episodic memory) and factual knowledge (semantic memory; for criticism and modifications of this view of memory, see, e.g., Baddeley, 1999, chap. 2). The content of the long-term memory store will also determine how the incoming information is interpreted and what behavioral responses are elicited. In sum, what has become clear is that incoming information is modulated at every stage of the information-processing flow, finally resulting in an individual’s very own construction of reality.

The aspects of a situation an individual attends to, the interpretation of these aspects, and the behavioral responses that follow are largely determined by the individual’s history and previous experiences. It can be assumed that the cognitive systems are largely “shaped” during childhood (e.g., Cicchetti, 2002), when those neurological systems (frontal lobe, amygdala, and hippocampus) undergo major developmental changes that subserve attention and memory as well as other higher-order cognitive processes such as problem solving and decision making.

In the following, we describe cognitive processes that we think can explain parts of the association that has been

found between adversity and allostatic load/health damage. We introduce an information-processing model of adaptation to threatening information that highlights two different adaptation pathways that can lead to allostatic load. We argue that both pathways are likely to be found in individuals who grew up in disadvantaged and/or adverse environments and who lacked protective mechanisms that could counteract the influence of adversity.

An Information-Processing Model of Adaptation to Threatening Information

As described earlier, individuals growing up in disadvantaged environments frequently face threatening situations: instability, financial problems, limited residential choices, crime, conflict, social aggression, and so on. Some of these threats constitute absolute stressors (e.g., maltreatment, crime); others constitute relative stressors (e.g., instability, financial problems). As presented in Figure 14.2, the frequent encounter with threatening information will likely result in a cognitive system that reacts hypersensitively to threatening information. This is accomplished by an attentional system that is highly vigilant, because the individual is expecting threatening information. The expectation of threats and a bias toward interpreting situations as threatening is probably due to a memory system that contains a variety of highly interconnected and easily accessible threat-related information (Pollak & Sinha, 2002). A cognitive system that is biased toward the detection and processing of threatening information can be viewed as adaptive in the short run (allostasis), because an early and

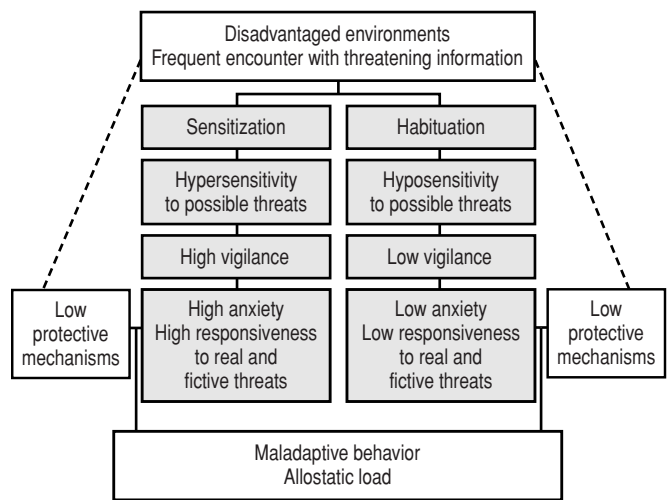

Figure 14.2 Schematic representation of how early adversity can modify the processing of threatening information, leading to habituation or sensitization of detection of threatening information.

facilitated threat detection might give individuals the necessary time to counteract the threat (Pollak & Sinha, 2002). This cognitive system, however, has at least two drawbacks in the long run. First, a hypervigilant system is likely to wear out quickly (allostatic load; McEwen, 1998b). Second, the cost of high vigilance is false alarms to relative stressors; that is, nonthreatening information might be falsely identified as threatening (Pollak & Kistler, 2002). Protective mechanisms, such as well-functioning parent-child relationships and cognitive abilities, are often compromised as a consequence of adversity. If protective mechanisms fail, sensitization to threatening information is likely to result in maladaptive psychological (e.g., stress, anxiety) and behavioral (e.g., aggressive, health-damaging) responses (e.g., Masten, 2001). Prolonged states of anxiety and anticipation of negative events can result in allostatic load (McEwen, 1998b).

One can think of another, and in some sense opposite way of dealing with frequent exposure to threatening information, namely, habituation (see Figure 14.2). Habituation is the tendency to become accustomed to a stimulus, resulting in the stimulus becoming less and less noticed. Individuals from disadvantaged environments might get accustomed to threatening situations and might filter out threatening stimuli. This can be adaptive in the short run, because the individual will be less anxious and less vigilant (allostasis). On the other hand, the late detection of and the general hyporesponsiveness to real threats prevent individuals from proactive planning of adequate responses. The consequence is that no stress response is initiated in situations where such a response would be adequate. The inadequate response of allostatic systems is one pathway that has been linked to allostatic load (Type 4 allostatic load, inadequate response; McEwen, 1998b). Furthermore, the hyporesponsiveness to threatening information might promote risk-taking and thrill-seeking behaviors that can lead to further health damage and greater allostatic load, especially when protective mechanisms fail.

Next, we review some empirical evidence for the adaptive processes described in the model. We describe studies that demonstrate the specific influence that adversity has on the development of several cognitive processes, including attention, perception, memory, language, and theory of mind. The research reviewed here comprises a rather heterogeneous set of studies covering very different aspects of adversity, from low SES to different kinds of child maltreatment. We are aware of the fact that different experiences lead to very specific outcomes. The heterogeneous sample of studies we describe serves the purpose of illustrating how the environment shapes cognitive processes in

such a way that the individual is more susceptible to stress, and is not meant to give a comprehensive overview of the complex literature on adversity and cognitive development. Throughout the chapter, the reader should keep in mind that high adversity alone has only a weak predictive value for poor developmental outcome. Only the combination of high adversity and weak protective resources leads to maladaptive profiles (Masten, 2001).

Before describing the studies, we briefly review the brain structures that are involved in the stress response and that might therefore be modified by early adversities. These brain structures play an important role in interpreting situations and selecting possible responses.

Brain Structures Involved in the Stress Response

Three brain structures are critically involved in the stress response: the prefrontal cortex, the amygdala, and the hippocampal formation. Each of these brain structures is affected by stress hormones and/or involved in the regulation of stress hormone secretion. At the same time, these brain structures play a crucial role in the interpretation of a situation (as being stressful) and in the subsequent selection and inhibition of possible responses.

The prefrontal cortex is sometimes described as the highest part of the brain as it is involved in most higher cognitive functions such as reasoning, planning, attention, working memory, and some aspects of language (e.g., Connolly, Goodale, Menon, & Munoz, 2002; Owen, Doyan, Petrides, & Evans, 1996). For instance, the prefrontal cortex determines which information will be considered and which information will be inhibited during the performance of goal-directed behaviors (e.g., Bunge, Ochsner, Desmond, Glover, & Gabrieli, 2001). It also plays an important role in retrieval processes, especially in recalling the temporal order and source of memories (e.g., Fan, Snodgrass, & Bilder, 2003). Many other specific functions of the prefrontal cortex could be named. Because of its involvement in nearly all higher cognitive processes, some authors regard the prefrontal cortex as the “frontal moral guidance system” that regulates social/moral behaviors (e.g., Bigler, 2001, p. 610).

The amygdala is critically involved in assessing the emotional significance of events (e.g., Anderson & Phelps, 2001). It is especially important for the processing of the emotions of anger, aggression, and fear. Recent studies with rats suggest that the amygdala also plays a crucial role in forming associations between cues and outcomes (Schoenbaum, Setlow, Saddoris, & Gallagher, 2003).

The hippocampal formation is involved in learning and memory. It specifically subserves the formation and re-

trieval of episodic memories, that is, the human ability to mentally travel back in time and remember where (spatial component) and when (temporal component) a specific event occurred (e.g., Tulving, 2002). During encoding, the hippocampal formation is engaged in relational learning mechanisms that bind the different components of an event into an integrated memory trace (e.g., Davachi & Wagner, 2002). Damage to the hippocampal formation results in profound amnesia, especially an inability to remember new episodes (e.g., Vargha-Khadem et al., 1997).

Roughly speaking, the described brain structures are critically involved in evaluating a situation and selecting an appropriate response (prefrontal cortex) with regard to the emotional content of the situation (amygdala) and in relation to past experiences (hippocampal formation, prefrontal cortex).

Selective Attention to Threatening Information in Maltreated Children

As described earlier, it is impossible to process all information to which an individual is exposed because attentional resources are limited. Therefore, some environmental cues are filtered out or attenuated and other stimuli are selected for further processing (e.g., Treisman, 1964). Which stimuli are attended to is a function of the physical and psychological state of the individual, as is the saliency of these cues. Children's information-processing capacities are much more limited than those of adults (e.g., Case, 1985). Therefore, they are much more selective in their attentional processes. Pollak and Sinha (2002) argue that children selectively attend to those features of the environment that are closely linked with highly positive or highly negative outcomes.

Pollak and colleagues (Pollak, Cicchetti, Hornung, & Reed, 2000; Pollak & Tolley-Schell, 2003) have demonstrated in several studies using a variety of methods that early experiences shape attentional processes and determine which stimuli children select for attention. They found that maltreated and nonmaltreated children differed in their attention allocation to certain emotional stimuli. Specifically, physically abused children were highly sensitive to information that signals threat and possible harm, namely, angry facial expressions. At the same time, these children had problems shifting their attentional focus away from angry faces; that is, they had less control over their attentional processes than nonabused controls.

Physically abused children are not only especially sensitive to anger cues, they also experience more fear than nonabused controls when witnessing angry interactions. For instance, in a study by Hennessy, Rabideau, Cicchetti, and Cummings (1994), physically abused children reported

more fear than nonabused controls when watching videotapes of adults in angry interactions. Over time, the frequent experience of fear and the accompanying stress response can result in allostatic load (e.g., McEwen, 1998b).

It is important to note that the studies by Pollak and colleagues (2000) show that abused children do not experience a general attentional deficit. Rather, abused children's attention is biased toward the detection of anger cues. Additionally, abused children have difficulties exerting control over their attentional processes when faced with threatening information. In the next section, we describe how this sensitization to threat affects perceptual and memory processes in abused children.

Effects of Adversity on Perceptual and Representational Systems

As described earlier, the long-term memory store contains an individual's knowledge about the world and past experiences. It can be hypothesized that the long-term memory store differs greatly in its content for children facing adversities when compared to children in less adverse conditions. Whereas children living in adverse conditions may experience a lot of stressful situations and daily hassles and acquire a lot of factual knowledge about how to survive in threatening environments, children living in more favorable conditions may experience a great variety of nonstressful situations. Thus, it can be assumed that the memory content of children facing adversity is biased toward threatening/stressful information. It can be further speculated that children facing adversity are more likely to interpret a situation as threatening and to select threat-oriented coping strategies, whereas children living in more favorable conditions are more likely to interpret a situation as nonthreatening and to select a nonthreat strategy to meet the situational demands.

The assumption that memory processes are shaped or fine-tuned by early experiences is again supported by the work of Pollak and colleagues (Pollak et al., 2000; Pollak & Sinha, 2002), who studied emotion recognition in children. Pollak et al. presented physically abused, neglected, and nonmaltreated children with several emotional stories. After hearing each story, the children were shown photographs depicting facial expressions of different emotions and were asked to select the photograph that would best fit what the story's protagonist felt. Neglected children, who have experienced a lack of care and responsiveness from their parents, had difficulties recognizing different emotional states. In contrast, physically abused children were as sensitive as controls in differentiating emotions, and they performed especially well in recognizing anger-related situations. Both

maltreated groups showed a response bias: Neglected children displayed a response bias for sad facial expressions, and physically abused children showed a tendency toward selecting angry facial expressions. This study clearly shows that early experiences shape how individuals interpret emotional signals in a very specific way. For instance, the response bias for anger in physically abused children might be due to their experience of frequent anger outbursts that are often unpredictable and that appear not to be related to the specific situation.

Physically abused children do not only show a response bias for anger. Already at a perceptual level, these children are especially sensitive to anger cues. This was experimentally shown by Pollak and Sinha (2002), who asked physically abused and nonabused children to recognize emotions from degraded pictures of happy, angry, sad, and fearful faces in a priming task. Faces were initially presented in highly degraded formats. Over time, the pictures became more organized and easier to identify. Physically abused children were able to correctly identify angry facial expressions on the basis of more degraded picture versions than were nonmaltreated children. Physically abused children needed more information than controls to recognize sadness. No group differences were found for happiness or fearfulness.

Taken together, these studies show that an abusive environment makes children especially sensitive for the detection of anger. According to Pollak and Sinha (2002), this is accomplished by a memory system that is fine-tuned by early experiences to allow for facilitated access to the representation of anger. Physically abused children grow up in an environment that is characterized by uncontrollable sudden outbursts of violence. The early detection of anger might give children additional time to prepare for hostile interactions. In this sense, abused children's early detection of threatening information can be viewed as adaptive. However, it becomes maladaptive when premature decisions about facial expressions are made (see Pollak & Sinha, 2002, for these arguments). In cases of uncertainty, abused children tend to interpret facial expressions as angry, a bias that restricts them from considering other possible interpretations (Pollak & Kistler, 2002). Later in life, a bias toward interpreting situations as threatening and therefore stressful is likely to result in allostatic load and situational-inadequate responses such as conduct disorders, aggressive behavior, depression, and anxiety.

Effects of Adversity on Language Development

Interpersonal communication is one mechanism that helps individuals to cope with stressful situations. This coping

mechanism is often spontaneously used with family and friends, and it is a basic element of many psychological counseling approaches (e.g., client-centered therapy; Rogers, 1951). For this coping mechanism to work, individuals need to be able to verbally express their problems and feelings; that is, communicative skills play an important role.

Language develops in a very constrained and predictable way in all normally developing children, and many researchers have emphasized the biological-maturational component of language acquisition (e.g., Chomsky, 1972; Pinker, 1994). This component might explain why individuals reared in very different cultural and linguistic environments all acquire their native language. Although almost all individuals become fluent speakers, environmental factors likely influence the grade of linguistic proficiency that is reached. It has been shown that disadvantaged environments can influence the pathways of language acquisition, possibly resulting in language and communicative deficits later in life. For instance, children from lower SES families show slower rates of vocabulary growth than children from higher SES families (Hoff, 2003). This effect is mediated by the speech children hear at home. Hoff showed that the speech of mothers from lower and higher SES differs in quantity, lexical richness, and sentence complexity, and that these differences explained over 20% of the variance in 2-year-olds' size of productive vocabulary.

Cicchetti and colleagues (Beeghly & Cicchetti, 1994; Coster, Gersten, Beeghly, & Cicchetti, 1989) looked at language development in maltreated children and found delays in language structure, expressive vocabulary, and expression of internal states. Eigsti and Cicchetti (2004) extended these findings by showing that not only the content but also the linguistic form is affected by maltreatment and SES: 5-year-old maltreated children and nonmaltreated children from low SES both scored below age-expected levels of syntactic abilities, with maltreatment causing a significantly greater amount of developmental delay.

What are the long-term effects of these developmental delays? Because longitudinal studies are missing, there is no definite answer to that question. However, Eigsti and Cicchetti (2004) suspect that language delays lead to later emotional, social, and cognitive delays and exacerbate existing problems. The observation that the speech of mothers from lower and higher SES differs in many aspects (Hoff, 2003) further supports long-lasting detrimental effects of disadvantaged environments on language skills. The less an individual is able to communicate his or her problems and internal states, the more difficulties he or she might have coping with stressful situations, because inter-

personal communication might not lead to the desired stress-releasing effect.

Effects of Adversity on False Belief Understanding

A 3-year-old child's understanding of the mind is very different from that of a 5-year-old child. Whereas 3-year-old children roughly assume that all people share the same knowledge, 5-year-old children have realized that people's beliefs may be true or false and that people's behavior is based on these beliefs rather than on reality. In their now-classic set of experiments on false belief understanding, Gopnik and Astington (1988) showed children of different ages a box with pictures of candy on it and asked the children what they thought was in the box. The children assumed that the box contained candy and were surprised when they opened the box and found crayons. When asked what another child who has not yet looked inside the box would think was in the box, 5-year-old children seemed to understand the concept of deception and said "candy." Three-year-old children, in contrast, answered that the other child would think that the box contained crayons. Moreover, 3-year-old children also denied their own original deception; that is, they said they had always thought that the box contained crayons. Since the original work by Gopnik and Astington several studies have shown that major changes in false belief understanding take place around 4 years of age (Wellman, Cross, & Watson, 2001).

Does false belief understanding follow a different developmental pattern in maltreated children? In a recent study by Cicchetti and colleagues (Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003), 3- to 8-year-old maltreated and non-maltreated children performed two false belief tasks. Among children with a verbal mental age of 49 months or greater, maltreated children demonstrated less false belief understanding than nonmaltreated children. Performance was worst for children who were physically abused and whose maltreatment started during the toddler years. Cicchetti et al. suggest two possible pathways by which maltreatment can affect false belief understanding. First, deficits in caregiving, especially the lack of parental empathy and sensitivity to the child's internal experiences, and the limited communication of feelings and emotions by the parents may contribute to a delay in the child's understanding of beliefs of self and others. This suggestion is strengthened by studies showing that maternal language to toddlers about internal states mirrors their children's abilities to become increasingly other-oriented (Beeghly, Bretherton, & Mervis, 1986; J. Dunn, Bretherton, Munn, 1987). Dunn and collaborators (J. Dunn, Brown, & Beard-

sall, 1991) found that individual differences in the amount of family discussions about feelings and emotions predicted young children's understanding of other people's feelings and beliefs, even when children's language skills were controlled for analytically. From these results, it is becoming clear that a child does not necessarily need to be exposed to significant adversities (e.g., maltreatment) in order to present weaknesses in the development of verbal abilities and emotional understanding, but that exposure to a family environment lacking the richness of interactions necessary to develop these skills may be sufficient to prevent adequate cognitive and emotional abilities later in life. Also, given the fact that the ability to make judgments about mental states is critical to social interactions, it may be possible that a lack of adequate development of this skill may prevent children from coping efficiently in the face of the various stressors of life.

Second, neurobiological maturation processes might be more directly altered by maltreatment in that "children subjected to pathological care giving may acquire neuropathological connections instead of functional neural connections" (Cicchetti et al., 2003, p. 1087). This pathway could explain why an onset of maltreatment during the toddler years is especially detrimental to the development of false belief understanding, because the toddler period is a time of rapid creation and modification of neuronal connections (see also Cicchetti, 2002), and many of the precursors of false belief understanding develop during that period, for example, language development (especially the verbal expression of internal states), conceptual development, increased individuation, and self-other differentiation (Cicchetti, 1991).

Regarding the influence of SES on theory of mind development, findings are somewhat mixed. For instance, Cutting and Dunn (1999) found differences in false belief understanding in relation to parental occupational class and mother's education (see also Pears & Moses, 2003). Other researchers have found that SES and performance in theory of mind tasks were not (Cicchetti et al., 2003) or only weakly (Murray, Woolgar, Briers, & Hipwell, 1999) related and that parental behaviors (Hughes, Deater-Deckard, & Cutting, 1999) or general and verbal intelligence (Murray et al., 1999) were better predictors of theory of mind performance.

Taken together, studies have shown that adversity can alter false belief understanding and other aspects of theory of mind development in children. For the case of maltreatment, the pathways through which maltreatment contributes to developmental delays have been specified. For low SES, the literature is less clear and the multifaceted

factors that may lead to successful or unsuccessful development need further specification.

Positive Outcome in the Context of Adversity: The Concept of Resilience

Not everybody reared in disadvantaged environments will face problems later in life. In the literature, the phenomenon that similar stressful experiences can lead to very different individual outcomes is referred to as multifinality (Curtis & Cicchetti, 2003). At the same time, not everybody who experiences problems later in life has faced adversity, a phenomenon referred to as equifinality (Curtis & Cicchetti, 2003). Both concepts highlight the important fact that early experiences do not ultimately determine further developmental pathways. This brings us to the concept of resilience. Resilience can be defined as successful adaptation or competent developmental outcome in the face of risk and adversity. Curtis and Cicchetti conceptualize resilience as “a dynamic process that is influenced by neural and psychological self-organization, as well as transactions between the ecological context and the developing organism” (p. 776). Thus, many different interdependent factors contribute to resilient functioning, including biological factors such as genetic makeup, brain organization, and neuroendocrine functioning; psychological factors such as emotion regulation, attachment, and locus of control; and environmental factors such as parenting (for overviews, see, e.g., Curtis & Cicchetti, 2003; Luthar, 2003; Masten, 2001). Here, we focus on cognitive processes that contribute to resilience.

An interesting longitudinal study on adversity and resilience was conducted by Masten et al. (1999), who followed children over 10 years from childhood through adolescence and assessed three major domains of competence: academic achievement, conduct, and peer social competence. Adversity was measured as the occurrence of major life events and experiences that are likely to be stressful (e.g., death of a family member). The study focused on two possible resources that are assumed to protect children from the effects of adversity: intellectual functioning (intelligence) and parenting quality. The authors found that both resources protected children from developing competence problems. High-adversity children with high intelligence scores and well-functioning parent-child relationships were as competent as low-adversity children. At the same time, low-adversity children with low resources developed competence similar to high-resource children. This shows that only the combination of high adversity and low resources resulted in competence problems. Specific to intellectual functioning, intelligence was related to academic achievement and to social competence

in childhood. Academic achievement is negatively associated with mental health problems (Sandler, 2001). Most interesting, high intellectual functioning in childhood was a protective factor against developing conduct problems in adolescence, thus pointing to the long-term moderating effect of early cognitive functioning on adversity. This finding also replicates previous studies that have shown that intellectual functioning is an important moderating variable of antisocial behavior in high-risk groups (White, Moffitt, & Silva, 1989). As Masten et al. (1999, p. 163) point out, “Numerous processes could underlie this effect: Good verbal, learning or problem solving aptitude could play a role in assessing threat, accessing resources, effective seeking of healthier environments or relationships for development, appealingness to teachers, etc.”

In summary, the data suggest that the capacity to detect threatening and nonthreatening information develops very early in life and is sensitive to environmental conditions. This modification of the selective attention process will lead to more threatening cues and information being stored in long-term memory, with the resulting effect that when the time comes to find a response to a threat (relative or absolute, real or implied), a threat-related type of response (aggression, violence, etc.) may be more readily available for immediate action. Although this response may be adaptive in the short run, the frequent detection of threat and/or threat response may lead to an allostatic load process, affecting the behavior, the body, and the brain. In terms of behavior, this decision process might lead in the long run to the development of externalizing behaviors and/or a diagnosis of a Conduct Disorder. If this is the case, then some bodily markers of allostatic load may be related to externalized behaviors in children.

To assess whether such a process might occur in developing children, we have reviewed the literature on externalized behavior and Conduct Disorders in children, in association with biological processes known to be involved in allostatic load. In our literature search, we found various markers of allostatic load that have been studied in relation to externalized behaviors or Conduct Disorders in children. Some of these biological processes are primary stress mediators (cortisol, DHEAS), and others are secondary outcomes (waist-hip ratio, cholesterol, and heart rate). We summarize these data in the following sections.

Allostatic Load and Externalized Behaviors/Conduct Disorder in Children

Conduct Disorder (CD) refers to a group of symptoms or problematic externalized behaviors. The description of CD

in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*), includes four types of behavior: (1) aggression toward people or animals, (2) destruction of property, (3) deceitfulness or theft, and (4) serious violations of rules; all of these are referred to as externalizing behaviors. Because it is a very heterogeneous disorder both in its occurrence and in its etiology, Frick (1998) proposed using the plural term Conduct Disorders. Two different types of CD are nowadays distinguished: the childhood-onset (*DSM-IV*) or life-course-persistent type (Caspi & Moffitt, 1995) and the adolescent-onset (*DSM-IV*) or adolescence-limited type (Caspi & Moffitt, 1995), each with a different etiology. The spectrum of CD also includes more extreme forms of behaviors, such as psychopathic behavior. It has been acknowledged that the distinction between these two types of CD is of importance for their causal accounts and treatment decisions (Caspi & Moffitt, 1995; Frick, 1998; Moffitt, Caspi, Harrington, & Milner, 2002). In our review of allostatic load markers, we focus on the childhood-onset or life-course-persistent type, and we intermix by sections the results of studies that have assessed either externalized behaviors in children or children diagnosed with Conduct Disorders. However, for the sake of clarity, we refer to only Conduct Disorders in each section's title.

Commonly, adverse environmental factors are suggested to contribute, at least partially, to the onset, maintenance, and exacerbation of externalizing behaviors among children (Haapasalo & Tremblay, 1994; McLeod & Shanahan, 1993). The adverse environmental conditions studied in relation to externalizing behaviors include SES (Brooks-Gunn & Duncan, 1997; McLoyd, 1998), low parental education attainment (Hanson, McLanahan, & Thomson, 1997), negative parental behaviors (Lempers, Clark-Lempers, & Simons, 1989), single motherhood (Corcoran & Chaudry, 1997), exposure to violence (Miller, Wasserman, Neugebauer, Gorman-Smith, & Kamboukos, 1999), and low quality of schools and neighborhoods (Bradley & Corwyn, 2002).

Here, it is important to note that the importance of these environmental variables in the development of externalized behaviors may stem from their actions on parental behavior. For example, economic hardship may decrease the mother's self-esteem (McLeod & Nonnemaker, 2000) and the parents' investment in the child (Bolger, Patterson, Thompson, & Kupersmidt, 1995; Jackson, Brooks-Gunn, Huang, & Glassman, 2000), may induce frequent use of physical discipline (Conger, Patterson, & Ge, 1995; Deater-Deckard, Dodge, Bates, & Pettit, 1996), and may exacerbate mothers' depressive symptoms (McLeod & Nonnemaker, 2000). So, the response that is induced by exposure to adverse en-

vironmental factors may be mediated by the psychological and physiological stress induced by these adversities, which in turn may be responsible for enhanced propensity to manifest externalizing behaviors (G. W. Evans, 2003; G. W. Evans & English, 2002).

A child who manifests externalization problems may react and cope (at physiological, cognitive, or behavioral levels) differently when confronted by threats as a function of his or her age. For example, a 10-year-old child with externalization problems may decide to either fight or lie to escape negative consequences, whereas an adolescent with externalization problems may be prone to select dangerous health-related behaviors (e.g., substance abuse, smoking) or adopt risk behaviors such as antisocial behaviors (e.g., stealing, fighting), drop out of school, or engage in sensation-seeking activities. From society's viewpoint, these behaviors may be unacceptable or at least impede access to better living conditions. Nevertheless, in the short run, some of these behaviors may enhance the child's or adolescent's perceived adaptation to threats by enhancing self-esteem or offering an alternative access to prestige or money, being recognized and respected, or having a thrill. Furthermore, children and adolescents manifesting externalized behaviors may also elicit more negative interactions and coercion from their environment. In attempting to adapt to threats in a cost-effective way according to their initial individual differences, some of them may exacerbate the likelihood of negative reactions from the environment, which could eventually lead to a sustained engagement in externalizing behaviors (Brennan & Raine, 1997). Thus, children with externalization problems may select different coping strategies from children without these problems as a result of both individual characteristics and adverse environmental conditions.

General Cognitive/Brain Dysfunctions in Conduct Disorders

The three brain structures (prefrontal cortex, amygdala, hippocampal formation) that are involved in the stress response (see earlier discussion) have been found to be structurally and/or functionally different in individuals with CD or other forms of antisocial disorders, including criminal psychopaths, when compared to normal controls.

With regard to structural differences, right temporal and prefrontal lobe volumes were reported to be smaller in early-onset CD and in Antisocial Personality Disorder (APD; Kruesi, Casanova, Mannheim, & Johnson-Bilder, 2004; Raine, Lencz, Bihrlé, LaCasse, & Colletti, 2000). Bigler (2001) put forward the hypothesis that the prefrontal cortex as the major instance of moral guidance never

developed a functional role in individuals with APD, thus explaining the deficiency of moral decision making in these individuals. It might be speculated that smaller prefrontal lobe volumes are also related to the impulsive behavior seen in individuals with CD and APD, because the prefrontal cortex plays a major role in response inhibition.

With regard to functional differences, Kiehl et al. (2001) showed that criminal psychopaths showed less activation of the amygdala and hippocampal formation when processing affective stimuli in comparison to criminal nonpsychopaths and controls. As described earlier, the amygdala is critically involved in fear processing and the formation of associations between cues and outcomes. The lower affect-related amygdala activation in criminal psychopaths therefore goes hand in hand with the finding that psychopaths are insensitive to several types of fear and punishment contingencies (e.g., Hare, 1965; Patrick et al., 1994). At the same time, in the study by Kiehl et al., criminal psychopaths showed an overactivation in the prefrontal cortex when processing affective stimuli. According to Kiehl et al., this overactivation might imply that criminal psychopaths need more cognitive resources to process affective stimuli.

As discussed earlier, allostatic load is intimately linked to brain integration of the environment. The interpretation of events as threatening or not leads to behavioral responses selected to cope with the threat, which in turn contribute to an increase of allostatic load in the long run (McEwen, 2000b). Children experiencing externalizing problems may modify *in their own way* (not necessarily consciously) their information-processing system (e.g., selection of coping behaviors and evaluation of their cost-effectiveness) to minimize the intensity/frequency of their subsequent reactions to further threats at physiological, attentional, and emotional levels. In other words, information processes may act to inhibit relevant events initially processed as threatening (habituation). As a consequence, physiological reactions induced by these initial threatening events may be reduced, leading to an allostatic response (inadequate response). This modification of the perception of threat will likely influence the physiological response of the child to environmental threats, which may then act to enhance externalizing behaviors through higher tolerance to negative events (e.g., punishment, pain, emotional arousal), reducing the child's response to social rules and frequent risky and sensation-seeking behaviors adopted by the child in order to cope with physiological underarousal (Raine, 1993).

We acknowledge that sustained externalizing problems during childhood and adolescence are not exclusively in-

duced through modifications of brain chemistry. Yet, a closer examination of the physiological markers related to allostatic load is a challenging and promising way to understand the mechanisms by which markers of allostatic load may relate to externalizing behaviors.

Cortisol and Conduct Disorder

Among all the components of allostatic load, the primary stress mediator cortisol has been the most widely studied in relation to Conduct Disorders in children. To this day, the most consistent finding with regard to the secretion of cortisol levels in children with CD is the presence of lower basal levels of cortisol, although some discrepancies in the results are clearly observable. The first study of children with CD was by Kruesi and collaborators in 1989 (Kruesi, Schmidt, Donnelly, Hibbs, & Hamburger, 1989). They measured 24-hour urinary cortisol excretion in 19 boys with Attention Deficit and/or CD and 19 age-, race-, and IQ-matched normal controls. The results revealed no difference in the 24-hour urinary cortisol secretion between the two groups. However, 2 years later, McBurnett and collaborators (1991) assessed salivary cortisol levels in 67 boys (ages 8 to 13 years) with Anxiety Disorders and/or CD. The results showed that children with both CD and Anxiety Disorder had higher levels of salivary cortisol than children with CD without comorbid Anxiety Disorder. After this first report of significantly lower cortisol levels in children with CD, a wealth of studies reported either a negative correlation between cortisol levels and symptoms of CD (McBurnett & Lahey, 1994; McBurnett, Lahey, Caspasso, & Loeber, 1996; McBurnett, Lahey, Rathouz, & Loeber, 2000; Pajer, Gardner, Rubin, Perel, & Neal, 2001) or the presence of significantly lower cortisol levels in children with CD when compared to children without CD (Pajer et al., 2001).

Although a significant number of studies have reported a link between low cortisol levels and Conduct Disorders, it is important to note that, similarly to Kruesi and collaborators' (1989) study, other studies did not report such an association. For example, in 1997, Schulz and collaborators (Schulz, Halperin, Newcorn, Sharma, & Gabriel, 1997) tested plasma salivary cortisol levels in aggressive and nonaggressive boys with Attention Deficit Disorder and reported no differences in cortisol levels between the groups. Other studies performed with adolescent mothers with CD did not report the negative correlation between cortisol levels and symptoms of CD (Susman et al., 1999) or did not report a significant difference between cortisol levels in adolescent mothers with or without CD (Azar et al., 2004). The discrepancy observed in the literature on cortisol and

symptoms of CD may stem from a variety of factors, including the diagnosis of CD, the externalizing behavior measured, and the time and method of assessment of cortisol. Indeed, in the various studies that were performed on the link between cortisol levels and Conduct Disorders, important methodological differences are observed, with some authors assessing the 24-hour urinary pattern of cortisol secretion (Kruesi et al., 1989), others assessing plasma cortisol levels measured immediately to 115 minutes after insertion of a catheter (Pajer et al., 2001; Schulz et al., 1997; Susman et al., 1999), and others assessing cortisol in saliva samples taken in the morning period (Azar et al., 2004; Vanyukov et al., 1993) or at any time (not controlled for) over a 2-year period (McBurnett & Lahey, 1994; McBurnett et al., 1991, 1996, 2000).

Here, we remind the reader that basal levels of cortisol follow a circadian cycle, with higher levels in the morning and declining levels throughout the day. It is thus extremely important when assessing cortisol levels in humans to control for the time of day at which the samples are taken. Moreover, any cortisol difference pertaining to samples obtained in the morning cannot be taken as direct evidence that cortisol secretion is lower in children with Conduct Disorders, given that it may be possible that the total excretion of cortisol throughout the day is not different in these children when compared to control children. Also, there is a major difference between plasma and salivary measures of cortisol, as the plasma concentrations of cortisol include both the free (biologically active) and bound (to carrier proteins and thus inactive) portions of cortisol, whereas salivary samples assess the free portion of cortisol. Given that it is the free portion of cortisol that will be active, salivary cortisol may represent a better measure of the biologically active cortisol levels than plasma cortisol levels. Moreover, cortisol levels have been shown to present a significant increase at 30 and 60 minutes after waking (called the cortisol awakening response; J. C. Pruessner et al., 1997), and this pronounced cortisol increase during the first hour after waking in the morning has been found to be associated with higher measures of self-reported stress (J. C. Pruessner, Hellhammer, & Kirschbaum, 1999; M. Pruessner et al., 2003; Schulz, Kirschbaum, Pruessner, & Hellhammer, 1998; Wüst, Federenko, Hellhammer, & Kirschbaum, 2000). Finally, venipuncture has been shown to induce a potent response of the HPA axis (Meeran, Hattersley, Mould, & Bloom, 1993), and it is possible that the cortisol response to venipuncture induces large inter- and intraindividual cortisol responses, explaining some of the discrepant findings. For a complete review of the methodological factors that could account for the discrepancies of data and for more in-

formation on the best method to assess cortisol levels in humans, see the recent review by Goodyer and collaborators (Goodyer, Park, Netherton, & Herbert, 2001).

Be that as it may, some mechanisms have been proposed to explain the link between low cortisol levels and externalizing behaviors. Low cortisol levels noted in aggressive individuals are understood in the light of an underaroused sympathetic autonomous nervous system and HPA axis (Lahey, McBurnett, Loeber, & Hart, 1995). Consequently, a dampened HPA axis secretion pattern would constitute an adaptive response (habituation) to aversive situations such as pain and parental coercive behaviors (Vanyukov et al., 1993). Moreover, lower reactive secretion in individuals manifesting externalizing behaviors may be explained as a higher HPA axis activation threshold (Kruesi et al., 1989). For these individuals, moderate stressful events may be inefficient to induce HPA axis activation. As a result, those individuals may feel understimulated and be prone to searching for sensation-seeking activities.

The low cortisol-CD link could also be interpreted as a physiological marker of a tendency toward (or an absence of) behavioral inhibition (Kagan, Reznick, & Snidman, 1987). Gray (1982, 1987) suggested that two neurophysiological systems are implicated in antisocial behaviors: the behavior inhibition system (BIS) and the behavior activation system (BAS). The BIS has received considerable attention in regard to the low cortisol levels noted in externalizing individuals. One of the main functions of the BIS is to down-regulate (inhibit) nonreinforced behaviors (e.g., aggressive behaviors) while perceiving aversive cues in the environment (e.g., punishment). BIS activation is expressed at the behavioral level through inhibition responses and at the physiological level in cortisol, serotonin, and noradrenalin secretion (King, Barkley, & Barrett, 1998). Convergent with the BIS, higher cortisol levels appear to be a protective feature against manifesting externalizing behavior problems (because facilitating inhibition of these behaviors), and lower cortisol levels may be a marker of a behavioral disinhibition already associated with externalizing behaviors (King et al., 1998; McBurnett et al., 1996).

Interestingly, most studies assessing the association between cortisol levels and the *development* of disruptive behaviors in preschoolers report a *positive* association between cortisol and some psychological correlates of externalizing behaviors (e.g., negative affect, aggression, difficult or instable temperament; E. P. Davis, Donzella, Krueger, & Gunnar, 1999; de Haan, Gunnar, Tout, Hart, & Stansbury, 1998; Gunnar, Tout, de Haan, Pierce, & Stansbury, 1997). For example, Dettling, Gunnar, and Donzella (1999) reported a positive association between cortisol

levels secreted during the day and negative affect and aggression in preschoolers. To explain this result, they suggested that immature regulation systems and negative peer relationships might be correlated with higher cortisol secretion. In this sense, the higher cortisol levels associated with aggression in preschoolers may be related to a stress-induced cortisol release rather than to basal levels of cortisol. Higher cortisol levels have also been interpreted as a marker of the effort to adapt to a demanding and unfamiliar social environment (Stansbury & Harris, 2000). Even though moderate cortisol secretion may enhance the child's capacity to cope with an unfamiliar environment, large secretions of cortisol may be a marker of dysfunctional social adaptation (McEwen, 2002). Consequently, an inverted U-shape relationship between cortisol and social functioning may best characterize this association in childhood (E. P. Davis et al., 1999) and adulthood (McEwen, 2003).

In the preschool years, the mechanisms involved in the modified HPA axis resulting from adverse environmental conditions remain to be clarified. The first years of life possibly constitute a sensitive period in which several physiological systems complete their maturation and show greater plasticity to environmental factors (De Kloet, Vreugdenhil, Oitzl, & Joels, 1998; Gunnar & Donzella, 2002). Consequently, adverse environmental conditions experienced during this sensitive period may be particularly determinant in inducing changes in the HPA axis (Heim et al., 2000; Meaney et al., 1996). Essex, Klein, Cho, and Kalin (2002) observed that children who experienced chronic stress during their 1st year of life have higher cortisol levels at 4.5 years of age, suggesting that cumulative rather than acute stressful events are linked to permanent physiological changes (G. W. Evans & English, 2002). Modified HPA axis secretion patterns observed in childhood and adulthood are thought to be one of several physiological outcomes of chronic stress experienced early in life (Gunnar et al., 2001; Gunnar & Vazquez, 2001).

Dehydroepiandrosterone and Conduct Disorder

DHEA and its sulfate (DHEAS) is another primary stress mediator that has been studied in relation to CD. The rationale here is that from around age 6, children exhibit a gradual increase in androgens, but these androgens are of adrenal origin, a period called the adrenarche. It is not until puberty that gonadal androgens (of gonadal origin), such as testosterone, become more important. Researchers (Buydens-Branchey & Branchey, 2004; Dmitrieva, Oades, Hauffa, & Eggers, 2001; Goodyer et al., 2001; van Goozen, Matthys, Cohen-Kettenis, Thijssen, & van Engeland, 1998; van Goozen, van den Ban et al., 2000) have thus concluded

that studies of Conduct Disorders in prepubertal children should therefore not focus on testosterone, but on adrenal androgens, such as DHEA and DHEAS. DHEA and DHEAS are also very interesting for the study of Conduct Disorders because, besides being secreted in the adrenal glands, they are also endogenously synthesized by the brain (Robel & Baulieu, 1995). Many studies have shown that DHEA acts by increasing neuronal excitability, enhancing neuronal plasticity and having neuroprotective properties (Wolf & Kirschbaum, 1999). From the effects of DHEA on the body and the brain, many authors have suggested that DHEA/DHEAS should be elevated in individuals who are aggressive. This suggestion has been confirmed.

In a study performed in 1998, van Goozen and collaborators examined the relationship between plasma levels of testosterone and DHEAS in 15 boys with CD and 25 normal controls boys. The intensity of aggression and delinquency of the boys were rated by parents and teachers over a period of 6 months. The results showed that boys with CD had significantly higher levels of DHEAS, although testosterone levels did not differ between groups. Also, the authors reported that levels of DHEAS were significantly and positively correlated with the intensity of aggression and delinquency as rated by both parents and teachers. The authors interpreted these results as suggesting that adrenal androgen functioning plays an important role in the onset and maintenance of aggression in young boys. In a second study, van Goozen and collaborators (van Goozen, van den Ban, et al., 2000) measured DHEAS in children with oppositional and antisocial behavior and normal controls. The results showed that children with oppositional and antisocial behavior had higher DHEAS levels than the control groups. An increase in DHEAS in children and adolescents with CD was also reported by Dmitrieva et al. (2001).

Cholesterol and Conduct Disorder

Cholesterol and, more generally, lipid concentrations and metabolism have received substantial attention in relation to externalizing behaviors and more specifically violence and delinquency. Interestingly, while allostatic load in adults and older individuals is associated with high cholesterol levels, a negative relation is usually noted between cholesterol and violence in both young and adults. Golomb, Stattin, and Mednick (2000) reported that low cholesterol levels in males were most frequently associated with violent crimes committed against others. The participants' age was related to both cholesterol levels and violent crimes, but the association remained significant when age was taken into account. Similar results were noted in relation to physical aggression (Hillbrand & Spitz, 1999; Hillbrand, Waite,

Miller, Spitz, & Lingswiler, 2000), past history of aggression in inpatients of a drug rehabilitation unit (Buydens-Branchey, Branchey, Hudson, & Ferguson, 2000), violent offenders with Antisocial Personality Disorder (Virkkunen, 1979), violent suicidal attempts (Vevera, Zukov, Morcinek, & Papezova, 2003), and cholesterol-lowering interventions in humans (Golomb, 1998; Muldoon, Manuck, & Matthews, 1990) and in nonhuman primates (Kaplan et al., 1994).

In contrast to the overall negative association generally reported between cholesterol and aggression, nonsignificant or positive relationships have been noted between cholesterol and psychological aggression, expressive hostility, and anger attacks (C. C. Chen, Lu, Wu, & Chang, 2001; Hillbrand & Spitz, 1999; Wing, Matthews, Kuller, Meilahn, & Plantinga, 1991). These results suggest that the cholesterol and aggression association is restricted to physical aggression and violence.

However, previous results obtained on the association between cholesterol and CD must be accepted cautiously for several reasons. First, most of these studies were conducted exclusively with male participants, which limits the generalization of results to females. A study conducted by Lindberg, Rastam, Gullberg, and Eklund (1992) reported a similar negative association between cholesterol and aggression in female participants, although the magnitude of the association was much weaker. Young age is related to the cholesterol-aggression association, but the link remains significant once age is taken into account, which suggests that the association between cholesterol and aggression is not essentially explained by the age of the child (Golomb et al., 2000). Note that alcohol use (linked to increased HDL level with no change in cholesterol) and SES levels (inversely correlated to cholesterol) do not explain the overall relation (Golomb, 1998).

The mechanisms connecting cholesterol to physical aggression are still unknown, but modified serotonin function has been proposed to mediate this association (Buydens-Branchey et al., 2000; Mysterud & Poleszynski, 2003). Low cholesterol levels reduce lipid microviscosity in the brain cell membrane, resulting in dampened activity in serotonergic systems (Kaplan et al., 1994; Vevera et al., 2003). Low serotonin levels are commonly related to a reduced capacity to inhibit aggressive behaviors and impulsivity (Coccaro, 1992; Linnoila & Virkkunen, 1992; Virkkunen, De Jong, Bartko, & Linnoila, 1989). Cognitive information and emotional processing are once again thought to be implicated in the serotonin-aggression association (Berman, Tracy, & Coccaro, 1997), namely by reducing sensitivity to external clues referring to punishment or norm violation (Spooont, 1992).

Other mechanisms have been shown to play a role in the aggression-cholesterol association. Negative mood states, low cognitive efficacy, and a reduced interpersonal involvement are also linked to low cholesterol levels in an inpatient sample (Hillbrand et al., 2000). These results suggest that the association between aggression and cholesterol may partially be accounted for by other psychological and behavioral correlates.

Waist-Hip Ratio and Conduct Disorder

Very few studies have assessed the link between waist-hip ratio and Conduct Disorders. In 2001, Ishikawa and collaborators (Ishikawa, Raine, Lencz, Bihrlé, & LaCasse, 2001) measured height, weight, body mass index, bulk, and psychosocial adversity in 44 controls and 43 adolescents and adults with antisocial personalities. They reported that adult antisocial individuals, regardless of age of onset, were significantly taller and had greater body bulk than controls. However, they also reported that although groups tended to differ on weight, they did not differ on body mass index. In 2003, Mustillo and collaborators assessed the association between obesity and the development of psychiatric disorders in 991 children ages 9 to 16 who were evaluated annually over an 8-year period for height, weight, psychiatric disorder, and vulnerabilities for psychiatric disorder. The results showed that of the four developmental trajectories of obesity tested—no obesity (73%), chronic obesity (15%), childhood obesity (5%), and adolescent obesity (7%)—only chronic obesity was associated with Oppositional Defiant Disorder in boys and girls and depressive disorders in boys.

Heart Rate and Conduct Disorder

Increased cardiovascular activity is a secondary outcome in the allostatic load model, which is operationalized by higher heart rate and blood pressure (both systolic and diastolic). Cardiovascular parameters (heart rate, blood pressure, etc.) are easy, noninvasive, and inexpensive to collect. Despite this apparent simplicity, it has to be noted that the context in which measures of heart rate are collected (resting rate or activation/anticipation heart rate) may have a major impact on the results obtained in a given study. This makes results harder to interpret and requires at least some caution. Also, very few studies have been conducted with children showing the full spectrum of Conduct Disorder. However, various studies have been performed on some of the externalizing behaviors present in Conduct Disorders. We summarize these two types of studies next.

A relationship between anger, hostility, elevated heart rate, and blood pressure has been noted in several studies (M. C. Davis, Matthews, & McGrath, 2000; Galovski,

Blanchard, Malta, & Freidenberg, 2003). Competition challenge, harassment, and provocative insults are thought to be central in the increased physiological reactivity associated with anger (Garcia-Leon, Reyes del Paso, Robles, & Vila, 2003). In contrast, instrumental and less emotionally aroused antisocial behaviors are associated with *lower* heart rate and have been suggested to reflect both an underarousal state and fearlessness (Scarpa & Raine, 1997). These sensation-seeking behaviors have been shown to enhance the propensity for risk-taking behaviors (e.g., alcohol and drugs, sexual promiscuity, extreme sports), physical aggression, and criminal activities (Raine, Venables, & Williams, 1995; Scarpa & Ollendick, 2003).

A meta-analysis conducted by Ortiz and Raine (2004) of 40 studies indicated that both resting heart rate ($n = 5,868$ with a mean age of 10.8 years) and reactive heart rate ($n = 578$ with a mean age of 12.6 years) were negatively related to antisocial behaviors. In their prospective study, Raine, Venables, and Mednick (1997) have reported that a low resting heart rate assessed at age 3 in 1,795 children was associated with higher rates of physical behaviors at age 11. Low resting heart rates have also been linked with fighting behaviors at age 9 to 12 years in children from low SES (Kindlon et al., 1995). This association is still significant when body size and pubertal status are taken into account.

Interestingly, it has been shown that stressful characteristics of inner-city environments, compared to suburban and rural area lifestyles and environments, are generally linked to higher blood pressure (Thomas & Groer, 1986). For some children, these adverse environmental conditions may sensitize them to further threats, contributing to increasing or maintaining higher resting heart rates. However, other children confronted with the same adverse conditions may be desensitized (habituation) to threatening events encountered on a daily basis. Convergent with this hypothesis, Cooley-Quille and Lorion (1999) reported that youths exposed to the highest levels of community violence have the lowest resting heart rate. Such physiological adaptation may be protective in the short run by dampening physiological activation associated with stressful environments, but it can become detrimental in the long run, placing these children at risk to engage in developmental trajectories characterized by externalizing problems such as delinquency and violence.

A second hypothesis for these discrepant results is that lower heart rates in aggressive and violent individuals may partially be explained through inherited differences in cardiovascular activity. Moderate to strong heritability estimates in cardiovascular indices are noted in several studies

in infancy (Dubreuil et al., 2003; Healy, 1992), childhood (Boomsma & Plomin, 1986; Schieken et al., 1989), and adulthood (An et al., 2000; Ditto, 1993; Somes, Harshfield, Alpert, Goble, & Schieken, 1995). Inherited differences in heart rate may enhance the propensity of individuals with lower heart rate to manifest externalizing behaviors while protecting individuals with higher heart rate from personal involvement in contexts where externalizing behaviors are adaptive or required (Kindlon et al., 1995; Raine et al., 1995). These working models appear at first sight hard to reconcile. Yet, although distinct, they are not mutually exclusive. From a developmental perspective, potential factors linked to the onset of externalizing problems are generally thought to be multidimensional and influenced simultaneously by genes and environment throughout one's lifetime.

Immune Function and Conduct Disorder

To this day, only one study has assessed the unique influence of Conduct Disorder on immune function. Birmaher et al. (1994) assessed total white blood cells, lymphocytes subsets, natural killer cell activity, and lymphocyte proliferation in adolescents with either Major Depressive Disorder or Conduct Disorder and normal adolescents. They reported that although there were no significant between-group differences in any of the cellular immune measurements, natural killer cell activity was significantly negatively correlated with past year and lifetime adverse life events across all effector-target cell ratios. This result remained significant after controlling for diagnoses and SES.

Allostatic Load and Conduct Disorder

Although the studies performed on the primary stress mediators and secondary outcomes of allostatic load have shown some associations with Conduct Disorders, it is important to remind the reader that the studies that validated the allostatic load model clearly showed that none of the components of allostatic load exhibited significant associations on their own with health outcome. Indeed, it was shown that it is the summary measure of allostatic load that is significantly associated with major health outcomes. These findings were consistent with the idea that although a modest deviation in the level of activity of a single physiologic system may not be predictive of poor future health, the cumulative toll from modest alterations in several physiologic systems is prognostic for poor health. Consequently, it may be possible that some of the discrepant findings related to primary stress mediators and/or secondary outcomes and CD may be due to the fact that only one com-

ponent of the allostatic load model has been assessed. Although no study has assessed all components of the allostatic load model in children with Conduct Disorders, recent studies measured two or more markers of allostatic load, and the results reveal a very interesting pattern of developmental allostatic load in childhood Conduct Disorders. We summarize these next.

Low Cortisol and High Sulfated Dehydroepiandrosterone in Conduct Disorder. As we have summarized, independent studies have reported low cortisol levels and high DHEAS in children with Conduct Disorders. This is an interesting finding because the opposite pattern is observed in depressed children ages 8 to 16 years, namely, high levels of cortisol and low levels of DHEA/DHEAS (Goodyer et al., 1996). A recent study performed in 2004 by Buydens-Branchey and Branchey assessed levels of cortisol and DHEAS in 40 adult cocaine addicts with a retrospective diagnosis of Antisocial Personality Disorder or childhood CD. Given that DHEAS and cortisol were assessed in blood taken with venipuncture, the authors attributed any group differences in DHEAS and/or cortisol to a difference in reactivity to the stress induced by the venipuncture. The results showed that the men who had a retrospective diagnosis of CD had significantly increased DHEAS levels and less cortisol in response to venipuncture. Comparisons between patients who did and did not meet the APD adult criteria did not reveal any significant difference in DHEAS or in cortisol responsivity.

Low Cortisol and Low Heart Rate in Conduct Disorder. Again, low cortisol levels and lower heart rate have been reported in children with Conduct Disorders, but very few studies measured these two markers at the same time in children with Conduct Disorder. In 2000, van Goozen and collaborators (van Goozen, Matthys, Cohen-Kettenis, Buitelaar, & van Engeland, 2000) investigated whether a pattern of lower autonomic nervous system and HPA axis activity can be found in children with disruptive behavior disorders under nonstressful and stressful conditions. They also assessed whether the pattern of hormonal responses to stress would correspond with the child's feelings of control and negative emotionality. In this study, they assessed cortisol levels, heart rate, skin conductance levels, and subjective feelings of control and negative emotionality in 26 children with disruptive behavior disorder and 26 control children. The results showed that in the baseline, nonstressful condition, heart rate and skin conductance levels were lower in children with CD, although cortisol levels were

similar in all groups. When exposed to a stressful situation, children with disruptive behavior disorders presented a lower increase in heart rate and cortisol, when compared to children without disruptive behavior disorder, but they reported higher levels of emotional arousal.

In a more recent study, Snoek and collaborators (Snoek, Van Goozen, Matthys, Buitelaar, & van Engeland, 2004) assessed heart rate and cortisol levels in children with Oppositional Defiant Disorder (ODD) and children with Attention-Deficit/Hyperactivity Disorder (ADHD) under baseline and stressful conditions. The results showed that under baseline conditions, the groups did not differ for cortisol levels, although the group of children with ODD presented lower heart rates than the ADHD group. The results also showed that in response to stress, children with ODD presented weaker cortisol and heart rate responses to stress when compared to children with ADHD and control children. Altogether, these results suggest the presence of a hyporeactivity of the primary stress mediators (cortisol and catecholamines/heart rate) in response to stress in children with ODD.

Cortisol and Immune Function in Conduct Disorder. In the immune system, white blood cells called lymphocytes are very diverse in their functions. The most abundant lymphocytes are the B lymphocytes (B cells) and the T lymphocytes (T cells). The B cells are designated as such because they are produced and mature in the *Bone marrow*, and T cells are designated as such because their precursors leave the bone marrow and mature in the *Thymus*. Chief among the regulatory T cells are helper/inducer T cells. These cells are needed to activate many immune cells, including B cells and other T cells. Another subset of regulatory T cells acts to turn off or suppress immune cells. There are two types of helper T cells. The Th1 type participates in cell-mediated immunity and are essential for controlling intracellular pathogens such as viruses and certain bacteria. The Th2 type provides help for B cells and, in so doing, are essential for antibody-mediated immunity. Antibodies are needed to control extracellular pathogens which, unlike intracellular parasites, are exposed to antibodies in blood and other fluids.

Glucocorticoids have been shown to regulate the expression of Th1 and Th2 (Chrousos & Elenkov, 2000; Elenkov et al., 2000; Elenkov, Papanicolaou, Wilder, & Chrousos, 1996; Milburn, Poulter, Dilmecc, Cochrane, & Kemeny, 1997). High levels of glucocorticoids have been shown to suppress Th1 and favor the expression of a Th2 response (a Th2 shift), whereas decreased concentrations of cortisol

produce a shift toward Th1 function and suppress Th2 (a Th1 shift; Chrousos & Elenkov, 2000; Elenkov et al., 2000). This is an interesting finding because Th2 shifts are associated with susceptibility to infections from most types of intracellular pathogens and vulnerability to cancer (Rabin, 1999; Shurin, Lu, Kalinski, Stewart-Akers, & Lotze, 1999; Sprietsma, 1999). In contrast, and although a Th1 shift has been shown to confer some protection from these problems, it has been associated with increased susceptibility to “stress-related” disorders such as fibromyalgia and chronic fatigue syndrome (Clauw & Chrousos, 1997; Crofford, Jacobson, & Young, 1999; Griep et al., 1998; Lentjes, Griep, Boersma, Romijn, & de Kloet, 1997; Scott, Medbak, & Dinan, 1998), as well as autoimmune (al-Wabel, al-Janadi, & Raziuddin, 1993; Balomenos, Rumold, & Theofilopoulos, 1998; Gutierrez, Garcia, Rodriguez, Rivero, & Jacobelli, 1998), and inflammatory (Chrousos, 1995; Harbuz, Jessop, & Lightman, 1997) disease.

Given that low cortisol levels have been correlated with a shift toward Th1 (predominance of Th1 with suppression of Th2), Pajer and collaborators (Pajer, Rabin, & Gardner, 2002) recently conducted a study in young girls with antisocial behavior to assess whether the low cortisol profile generally observed in children with Conduct Disorder is associated with a shift toward Th1. In this study, the authors used plasma levels of IgG3 and IgG4 as markers for Th1 and Th2 activity and assessed the IgG 3:4 ratios in 42 teenage girls with CD or controls. Results showed that the mean IgG 3:4 ratio was higher in the girls with CD and that cortisol levels were significantly and negatively correlated with IgG 3:4 ratio. These new findings indicate that immunologic abnormalities are present in relation to low cortisol levels in adolescents with CD.

The various studies that have been performed in relation to hormonal and immune dysfunctions in Conduct Disorders tend to show that lower levels of the primary stress mediators cortisol and catecholamines (through cardiovascular indices) are associated with Conduct Disorders and that these lower levels of activity are associated with higher levels of DHEAS and immune changes. It is interesting to note that the pattern of changes in the mediators of allostatic load is different from the pattern that has been observed in older adults. Indeed, in older populations, increased levels of the primary stress mediators cortisol and catecholamines and lower levels of DHEAS have been reported to predict functional decline later in life (Seeman, McEwen et al., 2001; Seeman et al., 1997). It is therefore possible that the differences in allostatic stress mediators reported to occur in children and older adults

may be due to differences in psychological characteristics of the populations (Conduct Disorders versus normal populations) or to significant developmental differences in the pattern of allostatic load across the life span (younger versus older adults).

Validation of Allostatic Load in Children

A very interesting study published in 2003 by G. W. Evans gives us very valuable data about normal childhood and allostatic load. Actually, this is the only study published to date that specifically assessed the various components of allostatic load in a population of children. In this study, 339 low-income children with a mean age of 9 were recruited from public schools in New York State. Evans evaluated the cumulative environmental risk factors using the same method previously described for physical environmental risk (crowding, noise, housing quality; see G. W. Evans & Marcynyszyn, 2004). Moreover, psychological risk factors (child separation, turmoil, violence) were also assessed, as well as aspects of the home environment and personal characteristics (poverty, single parenthood, maternal high school dropout). As well, two behavioral protocols were included to examine self-regulatory behavior and learned helplessness. The child's ability to delay gratification was used as an index of self-regulatory behavior, and learned helplessness was evaluated with a standard behavioral protocol. Finally, measures of allostatic load included resting blood pressure (diastolic and systolic), overnight urinary neuroendocrine measures (cortisol, epinephrine, and norepinephrine), an index of fat deposition (body mass index), and a total allostatic load index (0 to 6) reflecting the number of these six singular physiological indicators on which each child scored in the top quartile of risk. The results of this study showed that all three primary stress mediators (cortisol, epinephrine, norepinephrine) were elevated by cumulative risk exposure and that body mass index was significantly and positively related to cumulative risk exposure. More important, the author reported that the total allostatic load index was significantly related to cumulative environmental risk. Interestingly, it was found that children's own perceptions of self-worth were unrelated to any allostatic load indicators but were positively correlated with task persistence on the learned helplessness puzzle. Besides being the first study specifically assessing allostatic load in normally developing children, this study is very important because it shows that in low-income children without Conduct Disorders (although presence or absence of Conduct Disorder was not specifically assessed in this study), *higher* allostatic load scores on primary

stress mediators and secondary outcomes are observed. This is a very interesting finding in line with previous data summarized in children with Conduct Disorders, suggesting that when behavioral problems and/or symptoms become apparent in children, most markers of allostatic load are decreased. In his study, Evans tested the presence of a curvilinear function between cumulative environmental risk and allostatic load score, and the quadratic function proved to be significant. This result strongly suggests that a mechanism of early adaptation to allostatic load may exist, whereby the organism tries to adapt to environmental demands. As we have argued in previous sections of this chapter, this mechanism of adaptation may be closely related to the cognitive interpretation given to adverse events in order to adapt to the various challenges of life.

However, another possibility has to be raised with regard to the different results obtained on allostatic load in various populations. Indeed, it is quite possible that these different patterns of allostatic load are due to genetic influences acting on the stress mediators, leading to increased risk for the development of CD during childhood.

McEwen and Stellar (1993) have highlighted the idea that, early in infancy, genetic predispositions and environmental factors contribute to laying down the individual differences in subjective perceptions attributed to a threat (relevant or not) and then physiologically responding to it. As a result of cumulative threats (or less intense experiences) over time, initial differences in the response to stressful events could be altered (either minimized or enhanced), resulting in vulnerability to diseases (Repetti, Taylor, & Seeman, 2002; Rutter, 1994). To date, researchers in developmental psychopathology have devoted great effort to studying the associations and mechanisms linking early proximal (e.g., parental behaviors, parent-child relationships) and distal (e.g., poverty, dangerousness of neighborhood) environmental characteristics and the individual differences of presenting pathology. Results obtained from animal models (Meaney et al., 1991) and studies conducted with humans (G. W. Evans, 2003; Felitti et al., 1998; Gunnar et al., 2001; Hertsgaard, Gunnar, Erickson, & Nachmias, 1995) show promising features in our understanding of the trajectories leading to allostatic load. Less is known about the potent influences that genetic factors may have on allostatic load.

Considering that allostatic load is a complex syndrome involving several physiological mediators, regulatory systems, and stress-related structures (Repetti et al., 2002; Seeman, McEwen et al., 2001; Seeman, Singer, Ryff, Dienberg Love, & Levy-Storms, 2002), the estimation of the

overall impact of genes on allostatic load appears premature and questionable for several reasons. First, no empirical evidence allows for the assumption that individuals are similarly characterized across primary mediators: Are individual differences in primary mediators correlated? Second, primary mediators may have distinct trajectories leading to diseases: Does a dysfunction of the HPA axis induce a similar vulnerability for anxiety-related problems compared to an altered catecholamine system? Third, primary mediators may show different etiological patterns: Are primary mediators regulated by common or different genes/environments? Are primary mediators regulated by the same genes/environments across the life span? Current data show that genetic influences on some phenotypes might be enhanced during development, whereas the genetic influence on other phenotypes might be “turned on” or “turned off” later in life (Plomin, DeFries, McClearn, & McGuffin, 2001). Finally, considering that allostasis and allostatic load are probably multifactorial (e.g., influenced by several genes and environments), as are most complex phenotypes, the remaining question in estimating genetic and environmental influences on individual differences in allostatic load should be considered cautiously. Accordingly, the genetic influences on allostatic load could be more efficiently understood through studying their impact on more elementary neurobiological traits, such as primary mediators (de Geus, 2002). That is, primary mediators may be referred as endophenotypes of allostatic load, which allows a more valid examination of the respective roles of etiological factors (environments and genes) to each primary mediator (HPA axis, catecholamine, and DHEA) and consequently to the complex construct of allostatic load.

Genetic Influences on the Hypothalamic-Pituitary-Adrenal Axis: Results from Twin Studies

The HPA axis is one of the most studied primary mediators. Behavioral genetic analyses offer a powerful tool to investigate the etiology of individual variations for a trait in a population (D. M. Evans, Gillespie, & Martin, 2002). In behavioral genetic modeling, genetic and environmental sources of variance of a phenotype (or endophenotype) are disentangled by using measures collected from participants who differ in their degree of genetic relatedness (Plomin et al., 2001). In twin studies, genetic models are based on monozygotic (MZ; identical twins, sharing 100% of their genes) and dizygotic (DZ; fraternal twins, sharing approximately 50% of their genes) twin intraclass correlation comparisons. Typically, four main sources of variance can be

assessed and generally symbolized by the following capital letters (parameters): [A] represents the additive genetic effect (the effect of an allele is added to the effect of other alleles); [D] the nonadditive genetic effect (resulting from interaction between alleles at the same locus, *dominance*, or at different loci, *epistasis*); [C] the common environment effect, linked to the experience of similar environments within twin pairs; and [E] the unique environment effect, which also includes the measurement errors (Posthuma et al., 2000). In short, twin design studies allows us to estimate the magnitude of the genetic and environmental effects on a phenotype, and the mode of transmission (i.e., additive or nonadditive) that best reflects genetic covariation between participants (for extended description of genetic modeling in twin design studies, see D. M. Evans et al., 2002; Neale & Cardon, 1992; Posthuma et al., 2000). We highlight some empirical results of heritability reported from twin studies about individual differences in HPA axis (re)activity, underlining the main limitations and interpretations from a heuristic and methodological standpoint, and identifying future areas that will need to be investigated to initiate a comprehensive conceptual framework of modulatory influences of genes to allostatic load and psychopathology.

Large individual variations are noted in HPA axis (re)activity (Wüst et al., 2000). Genetic factors are thought to play an important role in the individual differences in HPA axis (re)activity. Surprisingly few studies have attempted to estimate the heritability of cortisol levels, although twin designs offer a great opportunity to assess genetic and environmental influences. Concerning nonreactive cortisol levels, reported heritability estimates vary considerably from one study to another, ranging from 0 to 74% (for a review, see Bartels, Van den Berg, Sluyter, Boomsma, & de Geus, 2003). Wüst and his colleagues have collected saliva samples after awakening on two consecutive days from 52 MZ and 52 DZ twin pairs ages 8 to 65 years old. They observed moderate genetic effects on saliva cortisol levels for the main increase in awakening cortisol response ($h^2 = .40$) and for the area under the curve ($h^2 = .48$). This finding is consistent with that of Kirschbaum and collaborators (Kirschbaum, Wüst, Faig, & Hellhammer, 1992), who reported a significant influence of genetic factors on the three baseline measures of salivary cortisol levels collected before stimulation procedures (CRH test, ergometry, and public speech). Meikle, Stringham, Woodward, and Bishop (1988) obtained similar heritability estimates with plasma cortisol levels ($h^2 = .45$ for total cortisol and $h^2 = .51$ for unbound cortisol) in 20 MZ and 20 DZ twin male pairs. Bartels, de Geus, Kirschbaum,

Sluyter, and Boomsma (2003) recently reported significant heritability estimates on cortisol levels sampled at several times on two consecutive days in 12-year-old twin pairs ($n = 180$). Results showed higher cortisol heritability estimates for samples collected 45 minutes after awakening ($h^2 = .60$), moderate estimates around noon ($h^2 = .30$), and null estimates in the evening. Other results also suggest moderate genetic influences for nonreactive cortisol levels (Inglis et al., 1999; Young, Aggen, Prescott, & Kendler, 2000). In spite of these results, other studies report null heritability estimates for basal cortisol levels (Froehlich, Zink, Li, & Christian, 2000; Meikle et al., 1988; Pritchard et al., 1998). Furthermore, some empirical results showed that the daytime cortisol profile is moderately influenced by shared environments (Wüst et al., 2000), although this finding appears inconsistent (Linkowski et al., 1993).

Heritability estimates of reactive cortisol levels (in response to stress) lead to divergent results, although most of them suggest no or minor genetic effects in cortisol responses to various stressful events or tasks (Nurnberger et al., 1982; Pritchard et al., 1998). For example, Kirschbaum et al. (1992) found no significant intraclass correlation differences between MZ and DZ twin pairs' cortisol levels in response to physical and psychological stress paradigms. In contrast, they obtained significant intraclass correlation differences during the administration of corticotropin-releasing factor (CRF; stimulates the HPA axis), suggesting that HPA axis responses to CRF may be influenced by genes via negative feedback retroaction loops. In these studies, no significant estimate of common environmental factors was reported.

Disparities noted for heritability estimates may be accounted for by various methodological procedures, such as collection methods (plasma, salivary, and urine samples), time of collection (at waking, before bedtime, before or after a stressful activity), and small sample size (Bartels, Van den Berg et al., 2003). Time of sampling and the nature of sampling (reactive or not) are particularly important as we are still unsure whether different genes may influence cortisol levels at different times of the day and what may be the common or different etiological factors related to nonreactive and reactive cortisol levels. Recent results suggest that estimates of genetic and environmental variance components vary sufficiently across the day to induce distinct etiological patterns of cortisol secretion at different times of the day (Bartels, de Geus et al., 2003). Why there are differences in genetic and environmental estimates in cortisol levels sampled at distinct times of the day is still unknown. Small sample size is another issue that could partially explain discrepancies between reported heritability

estimates. Most of these studies do not allow sufficient statistical power to distinguish the variance related to genes from the variance associated with common environments (Bartels, Van den Berg et al., 2003). As a result, genetic, common, and unique environment variance components are estimated, more often than not, through MZ and DZ intra-class correlations (except Bartels, de Geus et al., 2003; Bartels, Van den Berg et al., 2003). The main limitation of estimating heritability through rough comparisons of intra-class correlation is that it does not take into account the dispersion indices related to the evaluated phenotype. Moreover, this statistical procedure does not allow us to estimate confidence intervals and does not provide any statistical parameters that specify how well the chosen model (rather than other tested models) best describes the observed data (Posthuma et al., 2000).

To overcome these limitations, Bartels and her colleagues (Bartels, Van den Berg et al., 2003) have performed a simultaneous analysis by using structural equation modeling to fit data collected in five distinct studies selected on the basis of similar methodological characteristics (Froehlich et al., 2000; Inglis et al., 1999; Linkowski et al., 1993; Meikle et al., 1988; Wüst et al., 2000). A heritability estimate of 62% was obtained for nonreactive cortisol levels, suggesting that over half of the individual differences observed in basal cortisol levels can be attributed to additive genetic factors. The most parsimonious model includes no parameter for common environment. The remaining variance (38%) was attributed to uniquely experienced environment (i.e., environmental factors affecting the children within the twin pair differently). This result points to a moderate genetic component of basal cortisol levels across a large age span (i.e., 8 to 67 years old).

Theoretical Implications and Misleading Interpretations of Twin Studies' Results

No influence of the twins' shared environments on the HPA axis? In light of the results emerging from twin studies, one might be tempted to conclude that common environmental factors do not exert a significant influence on individual differences in nonreactive cortisol secretion. These findings are surprising given the fact that other studies have reported that adverse environments, including poverty, low parental education attainment, placement in orphanage, and parental negative behaviors, have a detrimental effect on cortisol levels and circadian rhythms (Flinn & England, 1997; Gunnar et al., 2001; Lupien et al., 2000; Taylor, Repetti, & Seeman, 1997). Can we reconcile these divergent conclusions? One interpretation may reside in distinguishing the characteristics of those studies from the twin

studies' samples. Bear in mind that environmental and genetic estimates can be interpreted only in the population from whom data have been collected (Plomin et al., 2001). No generalization of the results can be drawn to other populations. The majority of the heritability estimates reported in twin studies are issued from normative samples of twins mostly not confronted with intense and chronic stressful environments. Accordingly, the reported heritability estimates should not be extended or compared to clinical samples, which are particularly at risk in light of highly adverse environments, mainly because it is still unknown if there are relevant differences in genetic and environmental estimates that result from normative samples in comparison to clinical samples.

Another interpretation of the nonsignificant shared environmental factors reported by twin studies refers to different processes by which environmental factors may influence the HPA axis (re)activity at different periods of development. Infancy has long been conceived as a sensitive period of development mostly because several physiological systems have not completed their maturational processes and thus show considerable plasticity to environmental conditions (Andersen, 2003; De Kloet et al., 1998). Prenatal and early environments have been suggested to have important organizational and stable effects on primary mediators and, to a greater extent, on several regulatory systems, including the stress-related system (e.g., hippocampus, amygdala, hypothalamus; Repetti et al., 2002; Weinstock, 1997). Increased sensitivity to environmental conditions may allow the organism to achieve short-term or long-term adaptations to this environment (Huether, 1998; Teicher et al., 2003). However, the cost of stable modifications in stress-related systems, as induced by environmental factors experienced during the sensitive period, may not always be optimal, sometimes placing the organism in a long-standing allostatic load (McEwen, 2003).

Although the mechanisms associated with the permanent effects of early environments on individual differences in HPA axis (re)activity have not been fully understood, the role of glucocorticoid receptors is highlighted (Blackhurst et al., 2002; Takahashi, 1998; Welberg & Seckl, 2001). In rodents, postnatal handling during the 1st week of life has been shown to decrease stress reactivity later in life, perhaps through alterations in CRF gene expression in the paraventricular nucleus of the hypothalamus and the amygdala, resulting in increased glucocorticoid negative feedback via the glucocorticoid receptors (Meaney, 2001; Plotsky & Meaney, 1993; Vallee et al., 1997). In contrast, maternal separation occurring early in life induces increased HPA axis responses to stress that are

sustained in adulthood (Plotsky & Meaney, 1993). Alterations in CRF gene expression may contribute to this association. The effects in HPA axis regulation through manipulations of the pups' early proximal environments have been closely related to the overall modifications in time and/or quality of maternal care of the offspring (Champagne, Francis, Mar, & Meaney, 2003). Furthermore, mothers' individual differences in maternal care have been reported to have a nongenomic effect on HPA axis regulatory functions of their offspring, rather than inherited common genes related to the phenotype characterizing reactivity to stress (Francis, Champagne, Liu, & Meaney, 1999; Francis, Diorio, Liu, & Meaney, 1999). In other words, pups' individual differences in (re)activity are suggested to be genetically encrypted in their genotype, not through inherited characteristics but through epigenetic programming induced by maternal care (Weaver et al., 2004).

Can the results indicating an important influence of early environments to later HPA axis (re)activity be reconciled with those from twin studies indicating nonsignificant contributions of shared environmental factors? Note that the estimations of shared environmental factors' influence in twin studies are exclusively conducted from late in childhood to old age, thus, after the sensitive period highlighted in the studies that show considerable organizational effects of early environment to HPA axis (re)activity. This could explain, at least in part, some inconsistencies. Furthermore, bear in mind that behavioral genetic modeling estimating the sources of variance related to genetic and environmental factors in individual differences in HPA axis (re)activity are conducted without any specific consideration for the organizational effects of environments experienced during the sensitive period. To what extent those environments increase or decrease similarities within MZ and DZ twin pairs is therefore unknown. Taken together, these considerations underline the importance of adopting a prospective view of genetic and environmental influences in individual differences on HPA axis (re)activity. A closer examination of etiological sources of variance in individual differences in HPA axis (re)activity in infancy is then strongly needed because other mechanisms may be associated with individual differences in HPA axis throughout development.

Gene-Environment Interactions. Early environments have been shown to have organizational and long-standing influences in shaping individual differences in HPA axis (re)activity, particularly during the sensitive pe-

riod in infancy. After this period, individual differences in HPA axis (re)activity from both inherited and early environmentally settled genetic factors are suggested to interact with incoming environmental factors to determine the larger observed individual differences in HPA axis (re)activity (Anisman, Zaharia, Meaney, & Merali, 1998; McEwen, 2000a; Repetti et al., 2002). Interaction between genes and the environment refers to the idea that genetic factors influence the sensitivity of a given phenotype to distinct environmental settings (Rutter & Silberg, 2002). For example, a child who inherits a phenotype linked to high reactive responses to stress may be more vulnerable when confronted with more adverse stressful environments (e.g., environments exacerbate his or her genotype) relative to environments that do not present any significant stress factors. Bronfenbrenner and Ceci (1994) have gone beyond this assertion to specify that when synergistic effects resulting from genetic-environment interactions are weak, genetic potentials related to the phenotype (e.g., genotype) remain relatively unrealized. However, the potential should be progressively more actualized when gene-environment interactions become more stringent, specifically referring to more adverse stressful environments in association with HPA axis (re)activity. No twin studies have tested models including a parameter for the gene-environment interactions. In the context of significant genetic-environment interactions, the variance associated with the interaction factor is relegated to the genetic component, resulting in spurious inflated estimations of the genetic parameters and misleading interpretations about shared environment contributions. Further studies should address the conceptual and prospective processes related to individual differences in HPA axis (re)activity.

Unique Environments. According to the reported studies, a significant proportion of the total individual variance in the HPA axis (re)activity is consistently attributed to the unique environment parameters (Wüst et al., 2000). Unique environment components include, in addition to all measurement errors (e.g., sampling procedures and collecting time), environmental factors not shared within twin pairs. Nonshared environmental factors involved in the unique environment's estimate are theoretically unlimited, varying from different classes at school and distinct significant friends to more complex factors that constitute the cognitive processing of information. Confronted by similar threatening contexts, individuals may show different physiological responses according to the unique cognitive schemas activated and to the per-

ceived coping response availability and efficiency. Those nonshared environments contribute to increasing the non-shared source of variance estimated. However, these non-shared environmental factors may represent promising areas of interventions (e.g., cognitive therapy).

FUTURE DIRECTIONS

Based on our review of the model of allostatic load and our description of the potential effects of allostatic load on child development as a function of early adversity, we believe that there are two major issues that should be investigated in the next decade. The first relates to the importance of taking into consideration the hormonal milieu of the mother (both pre- and postnatally) when studying stress reactivity and allostatic load in children. The second relates to the importance of considering how early adversities can impact the developing brain and lead to increased reactivity to stress and/or trauma in adulthood.

The Hormonal Milieu of the Mother in the Prenatal and Postnatal Periods

Pregnancy is associated with major changes in hormone levels, and the post-partum period that follows birth is also associated with drastic modifications of hormone levels. Recent studies performed in both animals and humans suggest that the hormonal milieu of the mother in the prenatal and postnatal period might have significant impact on the child's development.

Prenatal Period

A growing body of empirical evidence, based on methodologically rigorous studies of pregnant women of different ethnic, socioeconomic, and cultural backgrounds, supports the premise that mothers experiencing high levels of psychological or social stress during pregnancy are at significantly increased risk for preterm birth or low birthweight (Hedegaard, Henriksen, Sabroe, & Secher, 1993; McLean et al., 1995; Paarlberg, Vingerhoets, Passchier, Dekker, & Van Geijn, 1995; Rini, Dunkel-Schetter, Wadhwa, & Sandman, 1999; Wadhwa, Sandman, Porto, Dunkel-Schetter, & Garite, 1993). Recent epidemiological studies in Europe, North America, and the developing world suggest that babies born at term with low weight (intrauterine growth retardation; IUGR) will develop with high prevalence several pathologies, including insulin resistance, Type 2 diabetes, hypertension, and ischemic heart disease, during adult life

(Barker et al., 1993; Phillips, 1998). It is interesting to note that the physiological disorders observed in low birthweight babies have all been associated with secondary outcomes of allostatic load in adult life (see earlier discussion). Such an association between IUGR and the appearance of diseases in later life has led to the fetal origin hypothesis (Barker et al., 1993), which suggests that adverse environmental factors acting in utero program the development of fetal tissues, producing later dysfunctions and diseases.

The effect sizes of maternal stress on birthweight in well-controlled prospective studies with large sample sizes (more than 1,000 women) have typically ranged between 1.5-fold and 2-fold increase (Hedegaard et al., 1993; Hedegaard, Henriksen, Sabroe, & Secher, 1996; Peacock, Bland, & Anderson, 1995). Most of these studies have shown that within the range of stressors that are related to low birthweight, the time of exposure to the stressor is the important variable. Chronic exposure to stress in the pregnant mother, more than exposure to acute stress per se, is the most important variable related to low birthweight in the child (Hedegaard et al., 1993; McLean et al., 1995; Paarlberg et al., 1995; Rini et al., 1999; Wadhwa et al., 1993). A human study performed by Wadhwa and collaborators found that, independent of biomedical risk, each unit increase of prenatal life event stress (from a possible sample range of 14.7 units) was associated with a 55.03 g decrease in infant birthweight and a significant increase in the likelihood of low birthweight (odds ratio = 1.32).

Programming is related to a specific time window during development and persists during the whole life span (Seckl, Cleasby, & Nyirenda, 2000). One reason the programming effects of prenatal environmental stress are permanent is assumed to be due to enduring effects on the HPA axis (Ader, 1969; De Kloet et al., 1998; Meaney, 2001; Meaney, Aitken, Viau, Sharma, & Sarrieau, 1989; Meaney et al., 1996; Menard, Champagne, & Meaney, 2004; Plotsky & Meaney, 1993; Weaver et al., 2004; Weinstock, 1997) and the resulting high secretion of glucocorticoids. Recently, it has been shown that these changes in programming are linked to alterations in glucocorticoid receptors in the limbic system (Lesage, Blondeau, Grino, Breant, & Dupouy, 2001; Levitt, Lindsay, Holmes, & Seckl, 1996; Lingas, Dean, & Matthews, 1999). Because the hippocampus contains high levels of glucocorticoid receptors and is an important regulator of glucocorticoid negative feedback (De Kloet et al., 1998; Jacobson & Sapolsky, 1991), it has been assumed that changes in receptor expression will potentially alter negative feedback thresholds within the HPA

axis, leading to chronically high levels of glucocorticoids in prenatally stressed individuals, which could in turn impact cognitive development in the child.

Indeed, rats exposed in utero to high levels of glucocorticoids have been shown to present significant memory impairments when compared to rats not exposed to stress in utero (Lemaire, Koehl, Le Moal, & Abrous, 2000; Szuran, Pliska, Pokorny, & Welzl, 2000; Welberg & Seckl, 2001). In humans, studies reveal an association between prenatal glucocorticoid overexposure and impaired cognitive development (for a review, see Buitelaar, Huizink, Mulder, de Medina, & Visser, 2003) and between stress during pregnancy and general cognitive development and language functioning in toddlers (Laplante et al., 2004). Both prematurity and IUGR are consistently associated with cognitive impairments (Buitelaar et al., 2003). Other data suggest that cognitive outcomes are more seriously compromised by growth restriction than by prematurity (Lagercrantz, 1997). Earlier studies, using more global measures of cognitive development, such as IQ tests, reported significant impairments among IUGR children (Breslau, Chilcoat, DelDotto, Andreski, & Brown, 1996; Hutton, Pharoah, Cooke, & Stevenson, 1997; Landry, Smith, Miller-Loncar, & Swank, 1997; Martyn, Gale, Sayer, & Fall, 1996; Seidman et al., 1992). As adults, IUGR babies are less likely to hold managerial/professional employment and earn less income (Strauss, 2000), suggesting that growth-related impairments in cognitive development are functionally relevant.

Altogether, these findings provide a strong set of data suggesting that exposure to stress in pregnancy might have a profound influence on birthweight and postnatal cognitive development, and consequently, that one could use an individual's birthweight/gestational age as a good proxy for exposure to prenatal early adversity. Future studies assessing the effects of maternal stress during pregnancy and reactivity to stress and cognitive function in the children should provide very valuable data on the effects of prenatal exposure to stress on allostatic load later in life.

Postnatal Period

Giving birth and caring for a newborn is a highly emotional and stressful experience for a new mother. Across all species, physiological and behavioral changes prepare the mother for the arrival of her offspring. In the past few decades, animal studies have documented considerable plasticity in the maternal brain during pregnancy and lactation (for a review, see Russell, Douglas, & Ingram, 2001). These changes, which span late gestation throughout lactation, ensure optimal infant development through

the establishment of maternal behavior (animal's nest building, retrieval, licking and grooming; reviewed by Numan, 1994), metabolic resetting, and neuroendocrine changes. During human pregnancy and the transition to lactation, major hormonal changes occur within a short period of time. Maternal levels of estrogens and progesterone, which increase gradually during pregnancy (about 10- to 20-fold for progesterone and 100-fold for estradiol concentrations), suddenly drop at delivery and return to pregravid levels within a few days. Just as in any other mammalian species, human maternal behavior and changes in mood, emotion, and cognition are then initiated in the preparation for motherhood (Russell et al., 2001).

Feeding Choice

It is interesting to note that earlier studies conducted in rodents have demonstrated that lactation is associated with a period of *hyporesponsiveness* to various stressors in mothers (Carter & Lightman, 1987; Higuchi, Honda, Takano, & Negoro, 1988; I. D. Neumann et al., 1998; Toufexis et al., 1998). More important, it has been shown that this period of stress hyporesponsiveness in mothers is associated with the same stress hyporesponsiveness period in pups (Dent, Smith, & Levine, 2000; Levine, 1994; Schapiro, Geller, & Eiduson, 1962). The main characteristics of this period in pups are very low basal glucocorticoid levels and an inability of many stressors to elicit a glucocorticoid response (Levine, 1994).

The presence of a stress hyporesponsiveness period in the mother is related to lactation (Hard & Hansen, 1985; Hary, Dupouy, & Chatelain, 1981; Lightman & Young, 1989; I. D. Neumann, Toschi, Ohl, Torner, & Kromer, 2001; Shanks et al., 1999; Stern, Goldman, & Levine, 1973; Walker, Lightman, Steele, & Dallman, 1992; Walker, Trotter, Rochford, & Lavalley, 1995; Windle, Brady, et al., 1997; Windle, Wood, et al., 1997; Witek-Janusek, 1988) and to the role of central oxytocin and prolactin release in discrete regions of the hypothalamus throughout lactation (for a review, see Torner & Neumann, 2002; Torner, Toschi, Nava, Clapp, & Neumann, 2002). Oxytocin and prolactin, respectively involved in milk ejection and production, not only have known anxiolytic effects in both male and female virgin rats, but also play an important role in the onset of maternal behavior (Bridges, 1984; Bridges, Numan, Ronshiem, Mann, & Lupini, 1990; Carter & Lightman, 1987; Higuchi et al., 1988; I. D. Neumann, Russell, & Landgraf, 1993; I. D. Neumann et al., 2001; Torner et al., 2002).

Humans differ from animals in their choice to breast-feed or not. In contrast to bottle-feeding, breast-feeding will initiate the hormonal response of oxytocin and pro-

lactin, which have been shown to be involved in the stress hyporesponsive period. Consequently, women who breast-feed may present a hyporesponsive response to stress when compared to women who bottle-feed. Such a result has been obtained in human mothers. For example, Wiesenfeld and collaborators (Wiesenfeld, Malatesta, Whitman, Granrose, & Uili, 1985) first showed that breast-feeding women exposed to infant signals display blunted autonomic skin conductance responses, compared to bottle-feeding mothers. Along with these findings, about a decade later, it was shown that, at 8 to 18 weeks postpartum, breast-feeding mothers have blunted HPA axis responses to a stressful treadmill exercise, compared to bottle-feeding mothers (Altemus, Deuster, Galliven, Carter, & Gold, 1995). These findings seem to suggest that women who breast-feed have blunted physiological responses to potentially stressful events. This could differentially impact reactivity to stress directly relevant to the infant and/or impact the child's hyporesponsivity to stress as well.

Consequently, it could be proposed that by inducing stress hyporesponsivity to environmental stressors, breast-feeding could serve as a protective factor for the mother (and possibly for her child) from repeated and/or excessive secretion of plasma and milk glucocorticoids during the postpartum period (Patacchioli et al., 1992; Yeh, 1984). In contrast, by preventing the emergence of the naturally occurring hyporesponse to neutral stressors, bottle-feeding might enhance the woman's reactivity to stressors and thus lead to repeated and/or excessive secretion of glucocorticoids. As we have summarized in this review, excessive secretion of cortisol levels in humans has been associated with memory impairments (Lupien et al., 1997, 2005; Lupien & Lepage, 2001; Lupien & McEwen, 1997; Maheu et al., 2004) and emotional disturbances (Sachar et al., 1973). Interestingly, a study published in 1992 reported a significant negative correlation between glucocorticoid levels and the mood of mothers who bottle-fed their babies (Bonnin, 1992). Breast-feeding is certainly not the only protective factor during this critical period, but as one that is easily accessible to all mothers, it might be one that could be strongly encouraged in specific populations exposed to high levels of environmental stress (i.e., low SES communities). These populations also choose more frequently not to breast-feed. It is thus possible that some of the effects of early adversities that are shown in children's development are due to the hormonal milieu of mothers at the time of birth of the child, induced by the feeding mode chosen by mothers. Clearly, further studies assessing the impact of infant feeding choice on the child's behavior are needed to elucidate this intriguing association between in-

fant feeding mode and stress reactivity in both the mother and her child.

Parity

Studies investigating stress responses have concentrated mostly on primiparous mothers, as the most dramatic changes in lifestyle occur after the first childbirth. Being a mother for the first time can at times be an emotionally intense and stressful experience in a woman's life. Even though fatigue and sleep disruption in maternal role "acquisition" in primiparous mothers is comparable to those experiences associated with the role of "expansion" in multiparous mothers (Waters & Lee, 1996), women with prior childbirth experience are less anxious and depressed (Fleming, Ruble, Krieger, & Wong, 1997; Fleming, Steiner, & Corter, 1997), undergo shorter and less painful labor (Mahon, Chazotte, & Cohen, 1994), and are less likely to experience gestational complications (Da Costa, Larouche, Dritsa, & Brender, 2000) and delayed lactogenesis in the days following delivery (D. C. Chen, Nommsen-Rivers, Dewey, & Lonnerdal, 1998), compared to primiparous mothers. In fact, parity is inversely correlated with the amount of life change (Grace, 1993). Thus, it is not surprising that multiparous mothers also display lower glucocorticoid levels during the days following delivery (Grajeda & Perez-Escamilla, 2002) and have more positive maternal attitudes and attractiveness to infant odors (Fleming, Steiner, et al., 1997). However, currently no study has investigated the changes in stress responsiveness as a function of parity. Future studies assessing stress reactivity in both mothers and children as a function of parity could lead to very interesting results.

Indeed, a few studies in the animal literature have investigated "habituation" of neuronal functions with respect to parity. This habituation process might also be present in the human population. Boukydis and Burgess (1982) observed higher arousal to infant cries in first-time mothers compared to mothers with several children and nonparents. This parity-induced attenuation in responsiveness is not surprising considering the fact that with repetitive exposure, the novelty characteristic of a stressful or emotional event is lost as the subject gains experience. This, in turn, can alter stress appraisal to the benefit of the mother, so that responsiveness to stress should be high only in situations of actual child endangerment. On the other hand, multiple demands placed on multiparous mothers increase fatigue (Sammons, 1990), which could enhance vulnerability to external stressors and lead to increased risk for postpartum depression (Righetti-Veltema, Conne-Perreard, Bousquet, & Manzano, 1998). Even though parity does not

play a significant role in occupational fatigue in working women (Newman et al., 2001), increased household demands, particularly linked to child care, can induce more daily stressful challenges and are linked to lower morning glucocorticoid levels (Adam & Gunnar, 2001). Interestingly, parity is also associated with elevations in the diastolic blood pressure observed during the daytime (James, Cates, Pickering, & Laragh, 1989), suggesting that multiple physiological systems, in multiple states (i.e., basal or stimulated), can be modified by parity. This result suggests that parity could have a significant impact on allostatic load in mothers and/or children.

Influences of Early Adversities on Brain Development

Every day, parents observe the growing behavioral repertoire of infants and young children, as well as the corresponding changes in cognitive and emotional functions. These changes are thought to be related to normal brain development, particularly to the growth of the hippocampus and frontal lobe regions from infancy to childhood. Results of various studies assessing developmental changes in brain structures showed that the volumes of whole brain and frontal and temporal lobes increase rapidly during the first 2 years after birth, followed by a more gradual expansion restricted to white matter (Matsuzawa et al., 2001; Pfefferbaum et al., 1994). Examination of the spatial and temporal patterns of brain growth, brain shrinkage, and cortical thinning over time may help to explain the cognitive and behavioral changes that occur from infancy to childhood. The volume of the hippocampal formation increases sharply until the age of 2 years (Utsunomiya, Takano, Okazaki, & Mitsudome, 1999), and the prefrontal volume increases rapidly between 8 and 14 years of age (Kanemura et al., 1999). Late growth in prefrontal volumes is consistent with data showing that this region is known to develop latest in terms of myelination and synaptic density (Yakovlev, 1967). In summary, by the age of 2 years, the hippocampal formation has stabilized, and the prefrontal cortex volume presents a sharp increase in volume by the age of 8. The observed maturation in the frontal lobes has been shown to correlate with measures of cognitive functioning during childhood and adolescence (Reiss, Abrams, Singer, Ross, & Denckla, 1996; Sowell, Thompson, Tessner, & Toga, 2001).

Although the changes in brain structures observed during childhood and adolescence are likely maturational in nature and may be related to pubertal and hormonal changes that occur during the adolescent years, it is impor-

tant to underline that, as summarized earlier, various animal studies have shown differential changes in dendritic arborization and cortical thickening of the hippocampus as a function of enriched, stressful, or demanding environmental experiences. It is thus conceivable that exposure to early adversities (prenatally and/or postnatally) in developing children might impact the development of the brain structures involved in the response to stress (hippocampus, amygdala, and frontal lobes; see earlier discussion) and lead them to become more reactive to stress in adulthood.

A recent study by Gilbertson and collaborators (2002) goes along with this suggestion. Earlier studies assessing the volume of the hippocampus in adult individuals who were exposed to traumatic events and who developed Posttraumatic Stress Disorder (PTSD) revealed that these individuals present smaller hippocampal volumes when compared to individuals exposed to the same trauma, but who did not develop PTSD (Bremner, 2002, 2003; Vythilingam et al., 2002). These results led to the suggestion that exposure to a traumatic event induces an atrophy of the adult hippocampus due to the neurotoxic effects of glucocorticoids on the hippocampus (the “neurotoxicity hypothesis” or “glucocorticoid-cascade hypothesis”; Jacobson & Sapolsky, 1991; Sapolsky, Krey, & McEwen, 1986). However, in 2002, Gilbertson et al. tested another possible hypothesis (called the “vulnerability hypothesis”), whereby *predetermined* smaller hippocampal volumes could explain increased reactivity to traumatic events in adults exposed to trauma, leading them to develop PTSD when exposed to a traumatic experience. To test this hypothesis, these authors measured hippocampal volumes in Vietnam War veterans who developed PTSD (PTSD+ group) and in others who did not develop PTSD (the PTSD– group) in response to the trauma of war. By comparing the hippocampal volumes of these two groups, they replicated earlier findings showing that the PTSD+ group had smaller hippocampal volumes than the PTSD– group (the neurotoxicity hypothesis). However, in the same study, they also measured the hippocampal volumes of the homozygotic twin brother of each of the Vietnam War veterans (PTSD+ and PTSD–), *who never went to war*. Here, they showed that the homozygotic twin brothers of the PTSD+ group *also* had small hippocampal volumes when compared to the homozygotic twin brothers of the PTSD– group. These results strongly suggest that the men who went to war and developed PTSD entered the war zone with a smaller hippocampal volume to begin with, relative to the men who went to war and did not develop PTSD (the vulnerability hypothesis). Consequently, hippocampal volume may actually be a preexisting condition that increases vul-

nerability to PTSD upon exposure to a traumatic experience, rather than (or along with) being a consequence of the trauma.

Still, the smaller hippocampal volumes in the men who developed PTSD on exposure to war could have been determined by early exposure to stress, which could then have delayed the development of this structure and rendered these individuals more vulnerable to the effects of stress and trauma later in life. Indeed, it is important to remind the reader that stress, environmental enrichment, and environmental demands are among the most potent inducers of changes in neurogenesis and/or dendritic arborization in the hippocampus, documented to lead to changes in hippocampal volumes.

Based on these data, we believe that there is an urgent need to test the influence of early adversity on the developing hippocampus (and other brain structures). Here, two contradictory hypotheses emerge with regard to the influence that early adversity might have on the development of the hippocampus. First, it could be postulated that children facing adversity due to lower levels of environmental enrichment and/or higher levels of stress could eventually present a delay in the development of the hippocampus (either due to a decrease in neurogenesis or a stress-induced decrease in dendritic arborization), which could eventually result in smaller hippocampal volumes in children facing early adversity when compared to children who do not. If this is the case, one could predict that smaller hippocampal volumes in children facing adversities could render these children more vulnerable to the effects of stress on both cognition and mental health. However, another hypothesis can also be proposed with regard to the development of the hippocampus in the face of adversity. Indeed, a wealth of animal data has now shown that hippocampal volume increases in relation to environmental *demands* due to the presence of stressful situations (see earlier discussion). It may thus be possible that growing up in adversity could lead to significant changes in hippocampal neurogenesis and/or growth and contribute to larger hippocampal volumes. If this is the case, one would have to predict that the larger hippocampal volumes in children facing adversity could render these children less vulnerable to the effects of stress on both cognition and mental health.

However, both hypotheses could coexist. Developmental pathways leading to small versus large hippocampi in children facing adversities could be determined by the child's perception of what the adverse environment can offer. If nothing is perceived as coming out of the adverse environment, stress could impact negatively on the developing hippocampus and lead to smaller volumes and to an

increased vulnerability to stress in future years. However, if exposure to adverse events pushes the child to search for more appropriate environments (increased demands), this could impact positively on the developing hippocampus, lead to larger volumes and, consequently, to a decreased vulnerability to stress in future years. If this is the case, then for the first time, a structural and biological basis of resilience would be described. However, the process that leads a child to believe that a neglectful environment has nothing to offer (learned helplessness) or that pushes him or her to search for a better environment (meeting demands) is one of the most intriguing processes that the field of developmental psychopathology might have to face in the next decade.

GENERAL CONCLUSION

The concepts of allostasis and allostatic load are inclusive of what we mean by stress, but they are much broader because they include aspects of lifestyle as well as genetic influences and developmental effects, including early life experiences and adversities. In this way, allostasis and allostatic load provide a general conceptual framework that allows us to evaluate the overall impact of the physical and social environment on individuals and groups of individuals. It should be emphasized that, although most of the work done so far has focused on the role of HPA activity and autonomic nervous system reactivity in these nature-nurture interactions, the allostasis/allostatic load model can be generalized to other physiological systems that respond to environmental stimuli. In other words, allostasis and allostatic load attempt to embody a general biological principle: that the systems that help protect the body and promote adaptation in the short term can also participate in pathophysiological processes when they are overused or inefficiently managed.

The most important feature of allostatic load is that it operates gradually over long periods of time in the life of an individual. In fact, as summarized in this chapter, influences of genetic factors and early experiences, when coupled with the subsequent life experiences of each individual, exert a lifelong effect on the physiology of an individual and alter the risk for developing a variety of pathophysiological conditions and diseases later in life as well as the rate of certain aspects of the aging process. More important, given that the primary stress mediators of allostatic load can access the brain, they can alter the way incoming information is processed, leading to important

differences in the interpretation of events as being stressful (threatening) or nonstressful (nonthreatening).

This multidisciplinary view of stress as a form of allostatic load should eventually allow us to identify very early in the life of an individual what are the potential risk factors for the negative effects of stress on physical and mental health. For example, personality traits such as anger, negative affect, low self-esteem, and emotional inhibition modify HPA and autonomic nervous system reactivity on an acute and/or chronic basis (for an example, see Kirschbaum, Prussner, et al., 1995). These changes, in turn, contribute to allostatic load when they represent a lifelong pattern of response to challenges. We have seen that these personality traits might themselves be the result of early life experiences as well as reflections of genetic factors. Fortunately, none of these traits, or the genetic and/or environmental factors that produce them, reflects an irreversible change in either behavior or allostatic load, and there are many intervention strategies that are likely to be very helpful early in development as well as later in life. However, before intervening in the early and/or later life period, one has to detect the presence of a chronic stress state. This is what allostatic load is about: detecting, in order to prevent.

How does children's memory operate and what are the critical developmental shifts during childhood that change memory from a less mature to a more mature system? How are these processes altered, if at all, in children experiencing trauma or psychopathology? In this chapter, we address these questions in the context of child maltreatment and the chronic stress and psychiatric sequelae associated with child abuse and neglect. Very solid theoretical grounds encourage us to anticipate that stress, particularly the stress associated with early aversive childhood experiences such as maltreatment, produces alterations in basic memory processes. Throughout this review, however, we show that the evidence does not substantiate such a claim.

Drawing on a developmental psychopathology perspective, we begin by discussing how childhood trauma might affect the normal course of memory development. Although there are scant data to date, there are a number of theories that lead us to believe that fundamental processes may be altered as a function of childhood trauma. In what follows,

we outline these theories and then evaluate them in the context of specific memory data related to children's basic memory processes and autobiographical memory. We conclude with a discussion of future research directions that should be undertaken to affirm or challenge our contention that, based on extant empirical findings, memory operates similarly in traumatized and nontraumatized individuals.

HOW DOES TRAUMA AFFECT MEMORY AND MEMORY DEVELOPMENT?

Trauma and the stress associated with it are thought to have a variety of effects on basic memory processes as well as on memory for traumatic events themselves. In an early description of the field of developmental psychopathology, Sroufe and Rutter (1984) stated ". . . the focus is on the ontogenetic process whereby early patterns of individual adaptation evolve to later patterns of adaptation. . . . At times, studying the course of adaptation in selected nondisordered individuals also is of great interest . . ." (p. 25). In a further elaboration of the parameters of the field, Cicchetti and Cohen (1995a, 1995b) highlighted the interplay between normal and atypical development and argued that investigations with both populations are

The writing of this chapter was supported by grants from the Natural Sciences and Engineering Research Council of Canada (to MLH), National Institute of Mental Health (to DC, MLH, and SLT), and the Spunk Fund, Inc. (to DC and SLT).

necessary to truly understand developmental mechanisms and processes. Therefore, in this chapter, we build on one of the central tenets of developmental psychopathology, namely, that investigations with normal populations can serve to inform approaches to atypical populations. Knowledge of the development of memory in normal populations of children provides a baseline with which similar or divergent memory processes in children who have been traumatized can be compared.

Because a number of reviews of the scientific and theoretical literature on the overall impact of stress on biological functioning (including the consequences of chronic Posttraumatic Stress Disorder [PTSD]) have recently appeared, we do not reiterate them here (see Bremner & Narayan, 1998; Bremner & Vermetten, 2001; Brewin, 2003; Dalgleish, 2004; Dickerson & Kemeny, 2004; Engleberg & Christianson, 2002; Kemeny, 2003; McEwen & Schmeck, 1994; Sapolsky, Romero, & Munck, 2000). Instead, we focus on specific aspects of stress responses that affect basic memory processes as well as those that are purported to affect memory for traumatic experiences themselves. We begin by providing an overview of physiological reactivity and stress, including a description of the measures most commonly used to index stress reactivity. This is followed by a synthesis of what is known about the effects of stress on the neural substrates of memory. In the penultimate section, we discuss theories and research concerned with acute versus chronic stress and memory development in childhood. We conclude by discussing clinical implications of this work and proposing directions for future research.

Physiological Reactivity and Stress

Stressful events frequently lead to the release of adrenal stress hormones, including catecholamines and glucocorticoids (McGaugh, 2000; Sapolsky et al., 2000). Studies with animals and humans have shown that the release of these hormones is correlated with dramatic changes in memory and cognition (Cahill & McGaugh, 1998; Lupien & McEwen, 1997; McEwen & Sapolsky, 1995; McGaugh, Cahill, & Roozendaal, 1996). Although exposure to acute stressors can enhance memory storage and consolidation (for a review, see Howe, 1998), impairment of memory and cognitive processes has been associated with chronic exposure to stressors (McEwen & Sapolsky, 1995). Clearly, however, the presence of either acute or chronic stressors can both enhance and impair memory and cognition depending on a number of factors, including the intensity of

the stressor (see Howe, 1998) as well as individual differences in stress reactivity (see Quas, Bauer, & Boyce, 2004). In what follows, we provide a brief overview of the basic mechanisms involved in biopsychological reactivity to stressors and show how these reactions enhance or compromise memory and cognition. We consider research with animals and humans and, in the latter case, with both adults and children.

Catecholamines and Glucocorticoids

It has been known for some time that physiological and psychological stress provoke an integrated response involving neural (including sympathetic and parasympathetic responses) and neuroendocrine (including the hypothalamic-pituitary-adrenocortical [HPA] axis) systems. The neural (sympathetic) contribution includes the secretion of the catecholamines epinephrine and norepinephrine, and the neuroendocrine contribution includes the secretion of glucocorticoids by the adrenal gland. A key similarity between these systems is that both catecholamines and glucocorticoids exhibit an inverted U-shaped relationship between the amount secreted and memory: Small amounts have little effect on memory, moderate amounts can enhance memory, and extreme amounts can impair memory (Gold & McCarty, 1995; Izquierdo & Medina, 1997; Korneyev, 1997; McGaugh, 1995). Although there is considerable debate as to whether such extreme levels exist in children's real-world experiences (see Chen, Zeltzer, Craske, & Katz, 2000), there are experimental studies that clearly show high levels to be deleterious to memory (see Sapolsky et al., 2000). Thus, stress can have seemingly opposite effects on memory depending on its intensity and chronicity. Further, these different effects can be either specific and experience-dependent (e.g., affecting only the specific event memory) or general and more globally relevant to basic memory processes (e.g., exhibiting long-lasting structural and functional consequences such as hippocampal cell loss or elevated levels of circulating catecholamines). In this chapter, we are concerned with both of these effects—the former because it addresses the issue of what can be remembered about traumatic experiences and the latter because it goes directly to the issue of how basic memory processes may be affected more generally by trauma and stress.

We should note that there are also differences in how catecholamines and glucocorticoids function. Catecholamines do not enter the brain directly but exert their effects indirectly (i.e., through secondary-messenger cascades at postsynaptic sites). Glucocorticoids directly af-

fect receptors especially in the hippocampus, a structure well-known to play an important role in learning and memory (particularly in the consolidation of memories). If this latter structure is permanently altered by glucocorticoid activity in response to stress and trauma, then questions arise concerning the longevity of memories from the traumatic experiences.

Two other distinctions between catecholamines and glucocorticoids are important. The first of these concerns the time course: The indirect effects of catecholamines develop over a relatively short interval (within seconds), whereas the glucocorticoids are secreted over a matter of minutes and their effects can take hours to emerge. Because memories are not formed instantaneously, taking a rather protracted time course to emerge (from hours to days depending on which model of consolidation one adheres to), both of these effects will be important but at different points in the time course of memory formation. The second difference concerns the site of their effects: Stress-induced catecholamine effects are localized primarily in the amygdaloid complex, whereas stress-induced glucocorticoid effects are localized primarily in the hippocampal complex (McEwen & Sapolsky, 1995).

Although different sites are affected, there is good reason to believe that both catecholamines and glucocorticoids can enhance or inhibit memory formation. That is, considerable evidence exists showing that the amygdaloid complex plays a central role in modulating (either enhancing or impairing) memories for stressful experiences (Cahill, 2000; Cahill & McGaugh, 1996; McGaugh, 1995, 2000, 2003; Pelletier & Pare, 2004). Similar memory-enhancing and memory-impairing effects have been observed with the stress-induced release of the endogenous glucocorticoids corticosterone (in rats) and cortisol (in humans), and these effects are believed to influence the neural processes linked to consolidation of memories (Diamond, Fleshner, Ingersoll, & Rose, 1996; Newcomer, Craft, Hershey, Askins, & Bardgett, 1994; Oades, 1979; Pugh, Tremblay, Fleshner, & Rudy, 1997).

Regardless of the locus of these effects, both catecholamines and glucocorticoids modulate what gets stored in memory and may do so by altering processes involved in consolidation (Abel et al., 1995; Cahill & McGaugh, 1996; Izquierdo & Medina, 1997). Consolidation is that process through which initially encoded information is transformed from its initial labile, transient form to a more stable, less volatile form (for a recent overview, see Dash, Hebert, & Runyan, 2004). More formally, consolidation refers to a phase of memory formation in which, among other things,

synaptic connections are strengthened, a process that is similar in duration at both the cellular and behavioral levels (for a more complete description, see Abel et al., 1995; Dash et al., 2004; McGaugh, 2003). Because it is during this consolidation interval that memories are most susceptible to interference and distortion, it is important to determine the length of this interval. Originally, consolidation referred to the stabilization of memory within the first few hours following encoding. Subsequently, it has been used to refer to a more protracted interval (months to years) that involves greater transformations, ones that may involve transfer of memory traces from one region of the brain (e.g., the hippocampus) to another (e.g., neocortex; Squire, Cohen, & Nadel, 1984). The modulatory effects of stress are thought to be relevant to the original sense of consolidation as most of the biochemical cascade effects occur over a briefer time course involving hours, not weeks, months, or years (Abel et al., 1995; Izquierdo & Medina, 1997). Thus, stress-induced release of catecholamines and glucocorticoids most likely modulate memories for traumatic events by altering (enhancing or inhibiting) the course of consolidation (also see Richter-Levin & Akirav, 2003).

However, there is some evidence that although glucocorticoids may act to enhance consolidation of memories, the same dose levels can act to inhibit subsequent retrieval of those memories. That is, stress-induced or exogenously administered glucocorticoids can have contradictory effects on memory, enhancing storage (consolidation) but inhibiting later retrieval. This is true even with acute doses of glucocorticoids. For example, de Quervain, Roozendaal, and McGaugh (1998) found that glucocorticoid doses sufficient to enhance consolidation profoundly impaired later retrieval. It should be noted that these effects have been obtained in spatial memory tasks with rats and may not generalize to humans.

Glucose and Oxygenation

Additional biological mechanisms can mediate the effects of stress on memory. In particular, catecholamine effects due to stress may arise because of changes in the delivery of oxygen and glucose to the brain. The catecholamine epinephrine, for example, may affect memory through its well-established effects on blood glucose. The modulatory effects of glucose on memory are, of course, dependent on a central cholinergic mechanism (Kopf & Baratti, 1995) and may be specific to the learning situation itself (Cahill & McGaugh, 1996). Specifically, when epinephrine release is experimentally blocked during an emotional episode (and glucose levels do not change), it is likely that β -adrenergic

receptor activation (by norepinephrine) may produce memory enhancement. In fact, the neurotransmitter norepinephrine, also important to memory, has been thought to enhance firing in neurons that participate in the encoding of environmentally significant information (Kety, 1970). Of particular importance, novelty is directly linked to norepinephrine release and subsequently enhanced retention in some animals (Kitchigina, Vankov, Harley, & Sara, 1997). In humans, blocking norepinephrine reduces the normal memory-enhancing effects of surprise (Cahill, Prins, Weber, & McGaugh, 1994; Nielson & Jensen, 1994). Relevant to this chapter, Cahill et al. found that the β -adrenergic blocking drug propranolol selectively impaired memory for an emotionally arousing story in healthy adults, supporting the claim that memory modulation due to emotional arousal is contingent on the activation of these β -adrenergic receptors even though they are not required for the formation of non-emotional (neutral) memories.

Effects of Prolonged Stress

Chronic stress (specifically, the release of glucocorticoids) in animals can lead to the atrophy of dendritic branches in the pyramidal neurons of the CA3 region of the hippocampus (Watanabe, Gould, & McEwen, 1992; Woolley, Gould, & McEwen, 1990). Although some of this loss is reversible, irreversible neuronal loss in the hippocampus does occur with prolonged exposure to glucocorticoids (Kerr, Campbell, Applegate, Brodish, & Landfield, 1991; Mizoguchi, Kunishita, Chui, & Tabira, 1992; Sapolsky, Krey, & McEwen, 1985; Uno, Ross, Else, Suleman, & Sapolsky, 1989). The fact that chronic exposure to stress-induced glucocorticoids affects dendritic branching first followed by neuron loss does not appear to be species-specific because such findings have been obtained in rats, monkeys, and tree shrews (McEwen & Sapolsky, 1995). Although studies with humans are less well controlled, they, too, suggest that hippocampal atrophy is associated with prolonged glucocorticoid exposure (Axelson et al., 1993; Starkman, Gebarski, Berent, & Scheingart, 1992). Indeed, it has been known for some time that prolonged exposure to elevated levels of glucocorticoids is accompanied by cognitive impairment, including impairment of declarative memory and visual episodic memory (Nasrallah, Coffman, & Olson, 1989). Although some of these findings with human participants are compromised because of coincident disease, studies with healthy adults have also shown that a decline in declarative (explicit) measures of memory, but not in implicit measures, can be associated with sustained increases in glucocorticoids (Lupien et al., 1994; Newcomer et al.,

1994; Wolkowitz et al., 1990). Functional magnetic resonance imaging (fMRI) studies with adults who have been exposed to prolonged stress, for example, abused women (Schacter, Koustaal, & Norman, 1996) and individuals who have been diagnosed with combat-related PTSD (Bremner, Krystal, Southwick, & Charney, 1995), as well as primates (Sapolsky, Uno, Rebert, & Finch, 1990) and humans (Keenan, Jacobson, Soleymani, & Newcomer, 1995) who have been exposed to elevated glucocorticoids over prolonged treatment intervals, show decreased hippocampal volume. Although this decrease may be subject to a variety of interpretations, it is possible that toxic levels of glucocorticoids were reached given the prolonged exposure to stress or to steroid (e.g., prednisone) therapy.

Although few studies have been conducted with children, it is known that high-dose prednisone treatment of asthmatic children leads to poorer verbal memory than low-dose treatment (Bender, Lerner, & Poland, 1991). In addition, maltreated children whose abuse is tantamount to chronic stress tend to exhibit altered patterns of diurnal cortisol activity. Specifically, depressed maltreated children, relative to nonmaltreated depressed children, exhibit lower concentrations of cortisol in the morning and show an increase rather than the normal decrease in cortisol from the morning to the afternoon (Cicchetti & Rogosch, 2001; Hart, Gunnar, & Cicchetti, 1996). There is additional evidence that children exposed to prolonged stress, including sexually abused girls (DeBellis et al., 1994), experience some deficits on explicit (declarative) memory tasks, although it is not clear that these problems are directly attributable to prolonged stress (Schacter et al., 1996). Although it is apparent that such individuals can have problems remembering (e.g., transient amnesia) aspects of the precipitating event (e.g., sexual abuse), it is also clear that they can have related deficits associated with the recall of autobiographical events (Kuyken & Brewin, 1995; Parks & Balon, 1995).

Individual and Developmental Differences in Stress Reactivity

As we have seen, traumatic events usually elicit high levels of stress hormones that are often maintained for a long period of time following the event (Sapolsky et al., 2000). This means that recently traumatized individuals should exhibit an exaggerated tonic level of arousal (e.g., elevated heart rate, hypersensitive startle response), something that leads to changes in information processing (e.g., attention may become narrowed and focused on a critical aspect of

the traumatic event—so-called weapon focus; Loftus, Loftus, & Messo, 1987). Information that gets encoded will be determined to some degree by this narrowing of attention, and what can be retrieved later is constrained by what was initially encoded (see Howe, 1997, 1998).

Thus, in general, there is a negative relationship between physiological arousal and attention, particularly in children (Richards & Casey, 1991; Suess, Porges, & Plude, 1994). In terms of children's memory and stress reactivity, reactive children have difficulty attending to external information when they are experiencing stress. This, in turn, limits information that gets encoded and stored; hence, memory traces may be more impoverished and less durable. Moreover, reactive children's arousal level can impact not only encoding, but also retrieval processes. That is, arousal levels may be too high for children to adequately search memory or utilize cues effectively (e.g., interviewer's questions or other available prompts). This is especially true when reactive children are being queried about stressful events or when the retrieval situation itself is stressful (see Quas et al., 2004).

But exactly how are these variations in stress and stress reactivity measured? Physiological reactivity has been measured in a variety of ways that reflect activation of the (1) autonomic nervous system (e.g., heart rate; respiratory sinus arrhythmia, an index of parasympathetic activity on the cardiac cycle; preejection period, an index of sympathetic activity on the cardiac cycle) or (2) HPA axis, most frequently operationalized in terms of salivary cortisol. As it turns out, measures of increased heart rate during the to-be-encoded event are negatively related to children's subsequent memory for those events (Bugental, Blue, Cortez, Fleck, & Rodriguez, 1992; N. Stein & Boyce, 1995). It appears that increased heart rate interferes with encoding, leading to impoverished representations of the event in memory. Although there are a number of limitations to studies such as these with children (see Quas et al., 2004), additional work using autonomic measures is clearly warranted, particularly investigations that also measure changes in heart rate during retrieval.

Considerably more research has used cortisol rather than variation in autonomic reactivity as an index of stress. For example, Merritt, Ornstein, and Spicker (1994) examined the relationship between salivary cortisol and a stressful medical procedure and found no relationship between cortisol levels and children's memory for the stressful event. Similarly, Chen et al. (2000) found no relationship between cortisol levels and children's memory for lumbar punctures. Unfortunately, the results of both of these stud-

ies are difficult to interpret given the relatively small sample sizes and the manner in which cortisol levels were calculated (Merritt et al., 1994) and because additional, potentially memory-relevant medications were present prior to the stressful procedure (Chen et al., 2000).

More recently, Quas et al. (2004) examined the interaction between physiological reactivity (autonomic responses and salivary cortisol) and social support (supportive versus nonsupportive interviewer style) on children's initial and long-term recollection of a stressful event (memory for an event involving a fire alarm). Although few significant relationships emerged at initial recollection, cortisol reactivity was associated with poorer long-term retention of the event. Moreover, autonomic reactivity was related to higher accuracy during a supportive interview and lower accuracy during a nonsupportive interview. It would seem that, at least in this study, autonomic and cortisol measures tap different aspects of memory processing for stressful materials (overall retention versus interview style), although both appear to be related to retrieval components of long-term retention.

Overall, the research on stress and memory with human and nonhuman participants suggests that both storage and retrieval processes are affected by stress. Although the results are often clearer in nonhuman animal studies, the results of the study by Quas et al. (2004) does suggest that retrieval of stressful memories is influenced by the type of interview being conducted and that overall retention levels may be influenced by children's stress reactivity. In terms of storage, although often difficult to demonstrate empirically with human child samples, "it seems reasonable that the storage of memories should be moderated in some way to enhance the contrast between memories of important events from those of less relevant memories—to enhance the distinction between signal and noise" (Nielson & Jensen, 1994, p. 190).

But why should it be so hard to demonstrate this connection between stress and enhanced storage or consolidation of information in children? As we have already pointed out, one reason is that a number of measurement issues exist when children are the sample of choice. In fact, with children, there is no consensus on the best index of stress. As previously discussed, a variety of techniques have been used to measure stress in children, including subjective self-ratings (where children rate their own level of stress), behavioral and objective rating scales (where parents or objective observers adduce the child's level of stress), physiological indices (heart rate, blood pressure, and the other indices listed earlier), and neuroendocrine measures (sali-

vary cortisol). Unfortunately, all of these measures have their weaknesses and have fared poorly with respect to predicting children's event memory. In addition to those studies already mentioned, Howe, Courage, and Peterson (1994, 1995) failed to find a relationship between self- or parent ratings of a child's stress and children's memory for emergency room treatment, even up to a year after the experience. Goodman and Quas (1997) also failed to find a relationship between subjective and behavioral measures of stress and memory for a stressful medical procedure, the voiding cystourethrogram (VCUG). Of course, the inability to find relationships between memory and stress as measured by subjective and behavioral scales may not be a surprise as such indices may be insensitive to the underlying physiological changes that are associated with stress (also see Howe, 1997, 1998). Thus, similar to the autonomic and neuroendocrine measures of stress reactivity, studies using subjective, objective, and behavioral scales have been unable to unambiguously link changes in children's stress with subsequent memory for those stressful events.

Another reason these measures, salivary cortisol in particular, may not predict event memory in studies with children is that the extent of these reactions can vary both developmentally and across individuals. For example, there are marked developmental and individual differences in cortisol responses to stress (for a review, see Gunnar, Tout, de Haan, Pierce, & Standbury, 1997). That is, neuroendocrine reactivity can fluctuate with other variables, including age, attachment styles (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996), temperament (Boyce, Barr, & Zeltzer, 1992; Kagan, 1994), stress reactivity (Gunnar et al., 1997), and knowledge (N. Stein & Liwag, 1997; for a review, see Howe, 1998). Salivary cortisol is a marker worth studying, especially because of its sensitivity to cognitive and social factors, as long as when it is examined, these other covariates are considered simultaneously. To do so, and to link cortisol and memory, Goodman and Quas (1997) pointed out that it is important to consider not only these individual differences, but also individual differences in the quality and quantity of memories for traumatic events. Frequently, such differences can be related to individual differences in the rememberer's reactions to and consequences from traumatic experiences (Brewin, Andrews, & Gotlib, 1993; Malinowsky-Rummell & Hansen, 1993). Thus, although a number of promising measures that may lead to a better understanding of the link between stress and memory in children exist, few studies have incorporated these measures into a single design. It is only when all of these individual differences factors are considered in concert that

relationships between neuroendocrine measures of stress reactivity and memory for stressful experiences will be discovered.

Effects of Stress and Trauma on Neural Development

Now that we have examined the extant research on physiological reactivity and stress in memory, we direct our attention to neural development. Specifically, what are the long-term consequences of prolonged stress, especially that associated with maltreatment, on neurological development? Although research on this question has really flourished only in the past decade or so, there is evidence that childhood physical and sexual abuse is associated with decreased cortical integration (Schiffer, Teicher, & Papanicolaou, 1995; Teicher, 1994), increased electroencephalogram abnormalities (Ito et al., 1993), and diminished size of the corpus callosum (DeBellis et al., 1999; Teicher et al., 1997). There is also evidence of similar, attenuated maturation of the corpus callosum in neglected children (Teicher et al., 2004). Moreover, studies have found that early maltreatment (neglect, physical and sexual abuse) exerts a larger negative impact on the developing corpus callosum in boys than in girls (DeBellis & Keshaven, 2003; Teicher et al., 2004). This gender difference was more important (accounting for more of the variance) than whether children developed PTSD as a function of the occurrence maltreatment. Thomas and DeBellis (2004) also found that the prolonged exposure to stress in traumatized children who develop PTSD is related to those children having greater differences in pituitary volume with age than that of control children.

Although it is not clear what these differences in neurological development might mean for the functioning of basic memory processes in neglected and abused children, some of the results concerning changes in hippocampal development are suggestive. For example, a number of researchers have found that maltreatment during childhood (physical and sexual abuse) is associated with diminished left hippocampal development in adulthood (Bremner et al., 1997; Ito, Teicher, Glod, & Ackerman, 1998; M. B. Stein, 1997) especially when it is comorbid with PTSD (Bremner, Vythilingam, Vermetten, Southwick, McGlashan, Nazeer, et al., 2003; Bremner, Vythilingam, Vermetten, Southwick, McGlashan, Staib, et al., 2003). Other investigators have not found changes in hippocampal volume as a function of trauma, even in those who develop PTSD (Bonne et al., 2001), and still other researchers have not found any support for the premise that hippocampal

development differs in maltreated and nonmaltreated populations (DeBellis, Hall, Boring, Frustaci, & Moritz, 2001; Pederson et al., 2004). Part of the reason for this discrepancy in outcome may have to do with the age of the maltreated subjects when examined; for example, in the Bremner et al. (1997) study, the participants were adults who retrospectively reported childhood abuse, whereas in the DeBellis et al. study, the participants were children whose abuse was documented. Caution is also needed when interpreting these outcomes because the sample sizes are often somewhat small (e.g., $n_s = 9$ maltreated and 9 control in DeBellis et al., 2001, and $n_s = 17$ maltreated and 17 control in Bremner et al., 1997).

Finally, some reports suggest an abnormal connectivity among brain regions involved in the recall of traumatic events in individuals who develop PTSD, but not in those who do not develop PTSD (Lanius et al., 2001, 2003, 2004). It may be that such dysregulation results in changes in how traumatic experiences are retrieved for people who develop PTSD, not in how or that such experiences are represented (encoded, stored, retained) in memory. Overall, then, although there is good reason to believe that the neurological substrates that subserve basic memory functioning should be altered as a consequence of early stressful experiences (e.g., child maltreatment), the empirical evidence is at best mixed.

EXTANT THEORIES OF MEMORY AND TRAUMA

This review of the cognitive neuroscience literature has shown that there are any number of reasons we should suspect that memories of trauma are somehow different from memories of ordinary events. As we have also seen in this review, although there is some evidence that individuals who develop PTSD may retrieve traumatic memories somewhat differently from those who do not, there is little evidence to suggest that the basic memory processes of traumatized individuals are somehow fundamentally different from that of other individuals. These facts notwithstanding, there exists theoretical speculation that victims of trauma may have fundamentally altered basic memory processes. In this section, we consider a number of these theories.

Terr's Theory

Contrary to what is known from the vast literature on memory, where amount remembered is directly related to the number of times one has experienced an event, Terr (1988, 1994) has suggested that memory for trauma is inversely related to the number of traumatic experiences a

person has encountered. That is, Terr believes that children often forget repeated traumas (what she calls Type II syndromes) but remember single traumatic experiences (what she calls Type I syndromes). Type I events revolve around a single incident, such as a kidnapping or schoolyard sniper attack, and tend to be memorable because they are distinctive inasmuch as they are unexpected and potentially life threatening. Type II events involve multiple repeated incidents of physical or sexual abuse and are not as memorable as Type I events because they are predictable and repetitive and become anticipated. Because such events become expected, children will employ defensive techniques such as denial and psychic numbing to reduce the emotional impact of these events, practices that in turn alter the encoding of these experiences such that later retention is difficult and such experiences become easily forgotten.

As has been shown in this chapter, the sorts of experiences Terr labels as Type I are, in fact, well remembered (for a review, see Howe, 2000). However, there is very little (if any) evidence that Terr's Type II events are forgotten or more poorly remembered. In fact, the only evidence that Type II experiences are not well remembered comes from Terr's (1988) own examination of 20 children's recollection of trauma they experienced prior to the age of 5 years. Of the seven who had Type II, repeated experiences, three were unable to verbally recall the events 5 months to 12 years later and four retained what were called "spotty" memories.

As others have pointed out, there are any number of reasons these conclusions about Type I and II event memories are flawed. First, Type I and II events were confounded with the child's age at the time of the trauma (also see McNally, 2003). That is, the children who could not produce verbal recall of Type II traumas were on average younger when their traumas ended than children who had single-incident Type I traumas. In fact, they were so young (6 months, 24 months, and 28 months of age) that many of these findings can be accounted for more parsimoniously by noting that this is exactly the time frame that is coincident with childhood amnesia (see Howe, 2000; Howe & Courage, 1993, 1997). Second, as Roediger and Bergman (1998) noted, the memory literature is replete with studies showing that repeated events are better remembered than one-time events. Although event repetition may lead to schematization of the memory, making some of the details concerning individual episodes difficult to discriminate, that such events are remembered and are remembered better than events that occurred only once is not in question. The extant literature on memory and repetition shows that the greater the repetition, the better the memory. Although

some might argue that such findings pertain only to non-traumatic event memories and that somehow the nature of traumatic events violates the general laws of memory, even in the context of traumatic experiences, most clinicians and researchers have found excellent recollection of repeated abuse (Goleman, 1992; Yapko, 1994), including physical (Pelcovitz et al., 1994) and sexual abuse (Archdiocesan Commission, 1990), community violence (Fitzpatrick & Boldizar, 1993), and horrific events such as the Cambodian holocaust (Kinzie, Sack, Angell, Manson, & Rath, 1986). Thus, contrary to Terr's notion that Type II repeated traumas are more poorly remembered than one-time events, there is abundant evidence that repeated abusive experiences are well remembered. Moreover, studies of intrusive memories of victims of abuse have clearly shown that people remember their abuse all too well (Ehlers et al., 2002; Hackmann, Ehlers, Speckens, & Clark, 2004; Holmes, Grey, & Young, 2005). In fact, it has been proposed that these involuntary memories occur in response to stimuli that bear a resemblance to stimuli experienced immediately prior to the traumatic event(s) and may serve as a "warning signal" (Charney, Deutch, Krystal, Southwick, & Davis, 1993; Ehlers et al., 2002; Foa & Rothbaum, 1998). Thus, Terr's idea contradicts what is known empirically. Indeed, all of the scientific evidence runs counter to Terr's assertions that the more children are abused, the more likely it is that they will forget having been abused.

Freyd's Betrayal Trauma Theory

Freyd (1996; Freyd, DePrince, & Zurbriggen, 2001) proposed that children are more likely to experience amnesia for abuse inflicted by parents or caretakers than by strangers because of evolutionary pressures to maintain attachments to those who are vital to one's survival. That is, it is adaptive to forget abuse that involves such betrayals of trust to ensure one's own survival. Although she agrees with Terr that repeated traumas are more likely to be forgotten, she does so because she believes that such abuse is more likely to have occurred at the hands of a caretaker. Thus, it is the status of the abuser (caretaker or stranger) that determines forgetting, not the number of abuse incidents.

As we have already seen and will see again later when all of the evidence is discussed, abuse tends not to be forgotten but rather to be remembered (Herman, 1981). In fact, Russell's (1999) epidemiologic study found that not one incest survivor had ever forgotten his or her molestation experience. Goodman et al. (2003) found no relationship between abuser status (parent/caregiver versus

stranger) and failure to report abuse years after the abuse. Thus, as for most, if not all, survivors of trauma, there is little or no support for the idea that incest survivors experience amnesia for their abuse.

Van der Kolk's Theory

According to van der Kolk (1994; van der Kolk & Fisler, 1995), trauma interferes with explicit (declarative), but not implicit, memory. This is because trauma leads to the release of stress hormones, hormones that create a sort of state-dependent memory for the traumatic experience. Further, van der Kolk argues that state-dependent memories are inaccessible to conscious recollection until the same state is induced again, and that until that time such memories remain intact and unchanged. That is, unlike other memories, van der Kolk maintains that traumatic memories are not subject to the normal deterioration processes that other memories are subject to; rather, they remain indelible. However, unlike explicit memories, implicit memories are said to appear spontaneously in the guise of flashbacks, dreams, body memories, avoidant behaviors, and so forth (Brown, Schefflin, & Hammond, 1998). Moreover, it is through these implicit memories that those who have been traumatized can "recover" an explicit memory of the traumatic experience.

This theory, too, is plagued by empirical and conceptual problems. First, as we have already discussed and will explicate more completely later, trauma does not prevent the formation of explicit, declarative memories. In fact, more often than not, stress aids the consolidation of memories for traumatic events. Although extreme levels of stress can impair consolidation, this does not result in memories that last forever, unchanged. Rather, it means that these memories do not get stored, so they cannot be recovered later. However, there is little evidence that such extreme levels of stress occur naturally. It is more likely, therefore, that such memories do get stored and that stress experiences enhance and promote the formation of explicit, declarative memory for traumatic events.

Second, even if trauma resulted in state-dependent memories that could not be accessed consciously, the evidence concerning state-dependent memories does not support the idea that such memories would be dissociated from consciousness. Specifically, research on state-dependent memories shows that although people tend to have less extensive access to those memories, they are not amnesic for the experience (Eich, 1995; Eich, Macaulay, Loewenstein, & Dohle, 1997). Of course, state depen-

dency cannot explain why memories of trauma would be recovered in a therapeutic environment that was presumably devoid of such trauma. Even individuals who report dissociative alterations in consciousness (e.g., slowing of time, out of body experiences) during traumatic events such as near-death experiences (for a review, see Greyson, 2000) or first-time skydiving (Sterlini & Bryant, 2002) do not become amnesic for these experiences, but are capable of providing detailed declarative recollections of such experiences.

Third, implicit memory does not contain an unchanging, veridical record of experience, traumatic or otherwise (see Howe, 2000). In fact, implicit memory is as subject to change and distortion as is explicit memory (Howe, 2000; Lustig & Hasher, 2001). Even if implicit memories did return as bodily sensations, unexplained feelings, and flashbacks, there is nothing in implicit memory traces that reveal their source. That is, such traces do not contain information that indexes their origin, and hence it is impossible to use them to accurately re-create the original experience. As Roediger and Bergman (1998) point out, sparsely encoded traces do not become more accurate with time. Instead, such traces undergo greater reconstruction, and hence are potentially more inaccurate, than more completely encoded traces. Moreover, such memories are not stored in muscle tissue—the idea of “body memories” is inconsistent with the cognitive neuroscience of memory, even the neuroscience of traumatic memories (see earlier section). In fact, animal research has shown that there is no such thing as indelibly etched emotional memories. Even well-established memories based on fear conditioning are labile and subject to alteration (Morrison, Allardyce, & McKane, 2002; Nader, Schafe, & LeDoux, 2000; Zola, 1997).

Foa's Fear Networks

It is well-known that many traumatized individuals develop a heightened sensitivity to trauma-related information (Field et al., 2001; J. M. G. Williams, Mathews, & MacLeod, 1996) as well as heightened memory for, and less forgetting of, trauma-related information (Amir, McNally, & Wiegartz, 1996; Cloitre, Cancienne, Brodsky, Dulit, & Perry, 1996; McNally, Metzger, Lasko, Clancy, & Pitman, 1998; Paunovic, Lundh, & Oest, 2002). Foa (Foa & Kozak, 1991; Foa & Rothbaum, 1998) has attempted to explain these phenomena by arguing that traumatized individuals, especially those who develop PTSD, develop semantic “fear” networks that serve to organize trauma-relevant information. These networks, like other semantic networks,

are developed to integrate information about a specific theme, in this case trauma, and may be used to alert their users to the warning signs of impending threat of trauma. Not only do these networks create states of hypervigilance, but they can also serve to preserve information about trauma (e.g., through rehearsal of information) and link similar experiences together in memory (making for stronger traces). Repeated traumatic experiences should, contrary to Terr, increase the likelihood of creating these networks, hence increasing memory for traumatic experiences. These networks are also said to be linked to intrusive memories for the traumatic experience(s).

There is some evidence supporting this idea. For example, it might be predicted that individuals who have been abused (e.g., childhood sexual abuse, or CSA) might have particularly robust CSA memories as PTSD symptomatology increases, with more severe abuse resulting in better CSA memory. This is exactly what Alexander et al. (2005) found: Individuals with documented CSA and individuals with more PTSD symptomatology had particularly accurate CSA memories. Thus, emotional events such as CSA may be better preserved in trauma-related semantic networks resulting in better, not worse, recollection later in adulthood.

Conversely, traumatized individuals who have subsequently developed PTSD should exhibit anxiety responses that are specific to trauma-relevant materials. Alternatively, PTSD may be the result of pathological memory formation (Keane, Fairbank, & Caddell, 1985) in which associative learning coalesces trauma-specific cues with neuroendocrine responses in what has been called a “fear network” (Foa & Kozak, 1991; Foa & Rothbaum, 1998; Foa, Steketee, & Rothbaum, 1989). The more an individual reexperiences the traumatic event, the greater the potential increase in tonic levels of sympathetic activation. This means that victims of recent trauma should exhibit fear responses to specific trauma-related cues (as the fear network continues to emerge) and that only individuals with chronic PTSD will exhibit generally increased levels of reactivity to all stimuli.

Recent reviews of physiological research with chronic PTSD patients have routinely concluded that these individuals have heightened responses to stimuli that are related to the traumatic event (Orr, Metzger, & Pittman, 2002). In fact, this pattern seems to hold for recently traumatized individuals as well (Elsesser, Sartory, & Tackenberg, 2004). That is, both recently traumatized individuals and those with chronic PTSD exhibited similar elevated levels of activation to trauma-related materials, but the groups did not differ with respect to levels of generalized activation.

In summary, although the theories that exist regarding the effects of trauma on memory have proffered some intriguing ideas and speculations, extant empirical studies do not substantiate the theoretical claims that traumatized individuals utilize fundamentally different memory processes than nontraumatized persons. These investigations are reviewed in a subsequent section of this chapter.

CHILDREN'S MEMORY DEVELOPMENT AND TRAUMA

Given all of the neurophysiological evidence and theoretical speculation we have just reviewed, there is good reason to expect that early trauma may result in changes so fundamental to the neural machinery necessary to encode, store, retain, and retrieve memories that the development of these basic processes will be compromised sufficiently to effect performance on everyday memory tasks. Indeed, a number of researchers have suggested that prolonged physiological reactivity to the effects of stress results in significant global changes in functioning during childhood, including increased risk of physical and mental disorders, emotional dysregulation, and cognitive dysfunction (Johnston-Brooks, Lewis, Evans, & Whalen, 1998; Porges, 1997; Raine, Venables, & Mednick, 1997; Rieder & Cicchetti, 1989; Scarpa, 1997). Despite the seeming obviousness of this linkage, there have been a number of failures to provide direct evidence of such a one-to-one mapping. Indeed, it seems more prudent to conclude that the mapping is one-to-many at best and, more realistically, many-to-many and that, rather than seeing reactivity as always being a risk factor, it is more appropriately conceived of as a form of biological sensitivity to environmental and contextual influences (also see Quas et al., 2004).

Despite these complexities, theoretical accounts of how basic memory processes might be compromised by early trauma do exist. Of the theories of memory and trauma we have just reviewed, only Foa's has received empirical support, but even here, this support has been limited. Although this theory, like the others just reviewed, is applicable to children as well as adults, none of the theories have explicitly addressed questions related to the potential changes to memory development that trauma and stress might produce. To address this question, we must first know something about the normal course of memory development. Because a complete exegesis would require numerous tomes, some of which have appeared recently (e.g., Brainerd & Reyna, 2005; Howe, 2000; Rovee-Collier, Hayne, & Columbo, 2001; Schneider & Pressley, 1997), we restrict

our presentation to those aspects of children's memory development most likely to be affected by stress, the sequelae of child maltreatment, and psychiatric disorder.

Development of Basic Memory Processes

To begin, a number of investigators have theorized that there is considerable continuity in basic memory processes across childhood and into adulthood (Bauer, 1996; Howe, 2000). That is, infants', toddlers', and children's memory, like that of adults, is subject to misleading information and false memories (Brainerd & Reyna, 2005; Rovee-Collier et al., 2001) and interfering information (Howe, 1995; Rovee-Collier et al., 2001), can be recoded once in storage (Howe, 2004b; Rovee-Collier et al., 2001), can be selectively "forgotten" when directed to do so (Howe, 2002), benefits from distinctiveness (Howe, in press; Howe, Courage, Vernescu, & Hunt, 2000; Rovee-Collier et al., 2001), and is subject to spacing effects (Dempster, 1988; Rovee-Collier et al., 2001) and to many other factors that are well-known in the adult memory literature. Although there is continuity in basic memory processes across development, there is also considerable growth. For example, memory improves as children's knowledge base increases (Bjorklund, 1987), as their ability to encode source information (the context in which information was acquired) improves (Drumme & Newcombe, 2002), as effective strategies (e.g., rehearsal, organization) improve (Schneider & Pressley, 1997), and as metamemory improves (Howe & O'Sullivan, 1990). This growth results in increases in the *complexity* of the information that can be retained, the *duration* of the interval over which information can be retained, and the *representational flexibility* of information in memory, as well as a reduction in the *context-specificity* of what is retained, to name a few outcomes (see Howe, 2000; Rovee-Collier et al., 2001).

Despite our ability to scientifically document these and other remarkable achievements in children's memory, the question remains: What is it that develops? That is, given the striking processing continuity that exists in the face of such prodigious growth, does there exist a common set of basic processes that underlie this dramatic growth in memory functioning and capacity? There is a singular dearth of theories concerning memory development, but those that do exist either emphasize neuroscience (i.e., advances in brain maturation) or cognitive science (i.e., advances in organizational efficiency) in their explanation of growth in memory throughout childhood, although these two approaches are not mutually exclusive. We next consider the

neuroscience explanations, followed by the cognitive science explanations.

The Neuroscience of Memory Development

According to C. A. Nelson (1995, 1997, 2000), improvements in memory during childhood are mediated by the extensive and rapid growth of structures in the brain. Specifically, Nelson argues that there are multiple memory systems (e.g., procedural versus declarative) that have different developmental trajectories. Some early developing neurological structures (e.g., the hippocampus, striatum, cerebellum, and olivary-cerebellar complex) are sufficiently well developed early in life to subservise a procedural, or what he calls a "preexplicit," memory system. This is the system that makes recognition memory possible, and it is the system that he argues is necessary for the types of memory performance seen in early infancy (e.g., novelty preference, habituation, operant and classical conditioning, visual expectancy). By contrast, performance on explicit, declarative memory tasks depends on the addition of later developing structures of the medial temporal lobe (e.g., the amygdala), inferior temporal cortical regions, and some aspects of the prefrontal cortex. These memory-relevant structures are not available until some time in the second half of the 1st postnatal year.

In addition, early life brings with it a number of ongoing neural developments, including proliferation of synapses, dendrites, fiber bundles, neurotransmitters, and myelin (see Johnson, 1997, 2000). In fact, the process of synaptogenesis peaks in infancy and toddlerhood and, following a period of overproduction, connections are pruned back and decline thereafter in early childhood (Huttenlocher, 1999). A key point for the purposes of this chapter is that experience is critical to this neural development. Specifically, the selective survival or loss of certain synaptic connections as well as the growth of new ones hinges on experience and interaction with the environment (Greenough & Black, 1999; Greenough, Black, & Wallace, 1987). Experience-based synaptogenesis and related changes in connectivity contribute to some of the neural infrastructure or hardware that supports advances in memory software (e.g., encoding, storage, retrieval). The extent to which and the manner in which different types of early experience affect neural development and hence the development of basic memory hardware and software is not well documented. Although this important area of investigation remains young, it is clear that a complete understanding of the development and malleability of basic memory processes early in life is contingent on

mapping the interaction of experience with the structural and functional plasticity of early neural development.

Cognitive Science of Memory Development

The ideas discussed in the previous section are not without their detractors due to some rather contentious assumptions. For example, some of the work has been conducted in brain-damaged adult populations or with lesioned animals. It is not clear that such findings generalize to intact, human children. Moreover, it is not at all clear that multiple memory systems exist. Indeed, there is evidence against this hypothesis (for a review, see Howe, 2000; Rovee-Collier et al., 2001). Even if there are multiple memory systems, it is not clear whether they develop sequentially or in parallel.

A good example of this debate concerns the idea that there exist separate implicit (i.e., nondeclarative memories that are said to be outside of conscious awareness) and explicit (i.e., declarative memories that are available to consciousness) memory systems. It has been argued that even though we may not have a conscious recollection of a traumatic experience, its residue nonetheless persists in our implicit, nondeclarative system and can still influence our behaviors, unbeknownst to us (for a brief overview, see Howe & Courage, 2004). The problem here is that extreme caution must be exercised when interpreting nonverbal behaviors (the quintessential index of implicit memory) as indices of memories of past traumatic events. This is because there is no direct mapping of specific traumatic experiences onto specific behaviors (e.g., a child's fear of loud noises cannot be inextricably linked to an earlier experience of hearing gunshots while witnessing the murder of his or her parents). Although it is important to remain open to the possible nonverbal behaviors that may signal memories for traumatic events, it is nonetheless prudent to be wary of the circularity of such observations (Howe & Courage, 2004). In any event, the available evidence suggests that even if there exist separate declarative and nondeclarative memory systems, they are both available and functioning very early in life and most likely develop in parallel (Howe, 2000; Rovee-Collier et al., 2001).

Because of these and other concerns about a pure neuroscience approach to memory development, cognitive science models of memory development (e.g., Brainerd & Reyna's, 2005, fuzzy-trace theory; Howe's, 2000, trace-integrity theory) have been constructed. Although these models were constructed independent of the ones just reviewed, they are consistent with findings in the neuroscience literature. For example, in fuzzy-trace theory, memory consists of two traces: a verbatim trace (one that

contains surface features of the experience as well as item-specific information) and a gist trace (one that contains the meaning of the experience as well as other relational, elaborative information). Although both types of traces develop early and in parallel, verbatim processing tends to dominate early in memory development, with gist processing becoming more dominant (depending on the task at hand) as development proceeds.

In contrast, trace-integrity theory views memory as consisting of unitary traces and memory development as a continuous process (Howe, 2000). This means that both verbatim and gist, implicit and explicit, procedural and declarative aspects of memory are contained within the same unified trace in memory. Differences in the retrievability of these different components of memory traces are controlled by trace integration and access features of the retrieval task and not by differences in the availability of different memory traces.

Regardless of which theory one adopts, the key to memory development is corresponding changes in organizational capacity. In fuzzy-trace theory, this may seem obvious inasmuch as gist processing begins to take on more and more importance as memory development unfolds. Perhaps the role of organization is equally obvious in the trace-integrity theory. Here, memory traces are viewed as collections of basic elements (e.g., features, nodes) that come to be integrated through processes linking the current functional information (that subset of features extracted and encoded from the current environment) with knowledge already stored in memory. Traces lie on a continuum from little or no integration to high integration, in which the elements within the trace have great cohesion and the trace itself is distinct from other traces in memory, making it highly discriminable for retrieval. The relationships among items or elements within the trace provides the “glue” for these traces. As children’s ability to organize and extract features from the environment grows, their ability to store and retrieve more durable traces increases. Because children’s ability to extract more and more abstract information from displays increases with conceptual development, as does their knowledge base, their ability to store and retrieve more conceptually sophisticated information also burgeons.

As an example, consider the onset of autobiographical memory or personal memories for events that happened to “me” (a more complete account is provided in the later section on autobiographical memory). It is well-known that before 18 to 24 months of age, children can remember events, but those events are not organized as events that happened to “me,” nor are they remembered in later childhood or adulthood (so-called infantile amnesia). Event memory can

become autobiographical only when there is a cognitive self (a me with recognizable features) that provides an organizational framework for storing and retrieving event information (Howe, 2004a).

Most theories of memory development concur that traumatic experiences should be well remembered due to their distinctive (e.g., emotional, unique) character (better discrimination of traces). The effects of chronic stress may be outweighed by effects due to differences in the semantic organization of experiences. That is, because maltreated children are often those who come from the lowest socioeconomic strata of our society, and because it is well-known that socioeconomic status (SES) is linked to differences in memory performance due to variation in knowledge base, it may well be that maltreated children’s basic memory processes are the same as those of nonmaltreated children (unless there is demonstrable brain injury) and differ only in the manner in which information is organized semantically (see Howe, Cicchetti, Toth, & Cerrito, 2004, for further discussion).

MEMORY DEVELOPMENT AND CHILDHOOD TRAUMA

The question as to whether childhood trauma alters the course of normal memory development is a difficult one to answer and is the subject of a number of ongoing research programs. In this section, we review what is known about this topic by addressing questions concerning the nature of children’s memory for stressful and traumatic experiences and whether there is any evidence that traumatized children’s basic memory processes have been altered by their trauma experience(s).

Children’s Memory for Stressful and Traumatic Experiences

A number of recent reviews have appeared on the topic of children’s recollection of stressful and traumatic experiences (e.g., Cordon, Pipe, Sayfan, Melinder, & Goodman, 2004; Howe, 1997, 1998, 2000), and all of them have concluded that, barring accompanying cerebral assault, children can and do remember many of the central elements of a traumatic event. For example, Howe and colleagues (1994, 1995) reported a series of studies in which young (18 months to 5 years) children’s memory for an accident and subsequent emergency room treatment was examined immediately (within 2 to 3 days of treatment), after 6 months,

and following a 1-year delay. Using free recall as well as open-ended cued recall, Howe et al. found that although details peripheral to the event were forgotten over time, the gist of the event was well remembered even after a 1-year interval. Interestingly, a subset of children who experienced additional emergency room experiences during the retention interval often blended these experiences into a single report (Howe et al., 1995). Although these intrusions did not retroactively interfere with recall of the original experience, an interviewer naïve to the original experience would not have been able to separate the information from the different experiences. Similar findings have been obtained in studies examining children's recall of medical examinations (Bruck, Ceci, Francoeur, & Barr, 1995; Ornstein, Shapiro, Clubb, Follmer, & Baker-Ward, 1997) and memories for anticipated painful medical procedures such as bone marrow transplants (Stuber, Nader, Yasuda, Pynoos, & Cohen, 1991), lumbar punctures (Chen et al., 2000), and the VCUg (Goodman, Quas, Batterman-Faunce, Riddlesberger, & Kuhn, 1994; Merritt et al., 1994). Overall, the findings from studies such as these converge on the conclusion that even recall of traumatic experiences is reconstructive and prone to the same type of errors commonly found in the recall of more mundane events.

Similar conclusions have been reached concerning children's memory for other, naturally occurring traumatic events. For example, children's memory for sniper attacks (Pynoos & Nader, 1989; Schwartz & Kowalski, 1991), hurricanes (Ackil, van Abbema, & Bauer, 2003; Bahrick, Parker, Fivush, & Levitt, 1998; Shaw, Applegate, & Schorr, 1996), earthquakes (Najarian, Goenjian, Pelcovitz, Mandel, & Najarian, 1996), a fatal bus-train collision in Israel (Tyano et al., 1996), attacks during the Gulf War (Dyregov, Gjestad, & Raundalen, 2002; Laor et al., 1997), and imprisonment in Cambodia (Kinzie et al., 1986), although accurate concerning the gist of the traumatic experience, is also subject to significant reconstruction. Not only do children tend to remember traumatic experiences reconstructively, but, like adults, they also experience involuntary, intrusive memories of these events (Malmquist, 1986; Pynoos & Eth, 1984). Such intrusive memories may serve as a warning signal that similar traumatic experiences are about to occur (see Ehlers et al., 2002; Hackmann et al., 2004).

Finally, children's and adults' recollections of childhood abuse (sexual and physical) are not only well remembered, but, as already noted, the probability of remembering tends to increase with the number of abusive incidents (Archdiocesan Commission, 1990; Goleman, 1992; Yapko, 1994). Like memories of natural disasters (Green et al., 1994), recollections of abusive experiences tend to be fairly durable,

being recallable many years later (see Alexander et al., 2005; Femina, Yeager, & Lewis, 1990; Loftus, Polonsky, & Fullilove, 1994; L. M. Williams, 1994). However, such recollections, like all recollections, are subject to reconstructive memorial processes.

Thus, the evidence indicates that, similar to memory for more mundane events, children's memory for traumatic experiences is good for central or gist information even though it is reconstructive in nature. One important difference may be that traumatic experiences are more durable than nontraumatic ones. The reason for this might be that traumatic or stressful memories carry with them some adaptive significance. That is, they can signal impending threat when the appropriate warning stimuli are present in the environment (e.g., Ehlers et al., 2002; Foa & Rothbaum, 1998). The preservation of such memories then helps to assure the organism's survival by assisting in the avoidance of similar threatening events (also see Wiedenmayer, 2004). In addition, such experiences are distinctive and personally significant, qualities that are well-known in autobiographical memory research (Brewer, 1986; Conway, 1996; Howe, 1997) for promoting longevity. More generally, naturally occurring distinctive experiences, as well as those created in the lab, are well-known to be better remembered than less distinct experiences (Howe, *in press*; Howe et al., 2000). Thus, there is considerable continuity in the memory processes governing recollection of traumatic experiences and those governing more traditionally studied memory experiences. The question that remains, however, is whether these general processes that govern memory and memory development are somehow altered by stressful and traumatic experiences, causing them to differ over time, particularly in children who have experienced chronic stress.

Traumatized Children's Basic Memory Processes

As previously discussed, autobiographical memory can begin as early as 2 years of age, the time at which the cognitive self emerges (Howe, 2004a). Although we will defer discussion of autobiographical memory until the next section, it is of interest to note that the clinical literature is replete with examples of nonverbal indices of traumatic memories from before the age of 2 years in traumatized infants (Gaensbauer, 1995, 2002; Paley & Alpert, 2003; Terr, 1988). Most of these infant memories are revealed during play therapy and, as cautioned earlier, need to be interpreted carefully. In fact, it is not clear that these nonverbal play behaviors represent actual memories as they require considerable prompting to be elicited, are heavily dependent on

context (events, places, people, etc.), and may be elicited because of the demand characteristics of the props and context (Cordon et al., 2004; see Howe et al., 1994, for a case study). Generally speaking, then, there is little evidence to substantiate the claim that traumatic experiences are retained, implicitly or explicitly, before the age of 18 to 24 months, and it is very clear that they do not become part of our adult memories for events (L. M. Williams, 1994).

By approximately 2 years of age, children are capable of remembering distinctive and traumatic events. Traumatized children are also capable of remembering events at this age (see the section on autobiographical memory), but the relevant question here is whether these experiences subvert the normal course of memory development. That is, do traumatized and maltreated children's basic memory processes begin to work in ways that are fundamentally different from those of nonmaltreated children?

This question has been addressed in only a handful of studies, most of which have been published only recently. For example, Eisen, Qin, Goodman, and Davis (2002) examined maltreated children's memory and suggestibility about an anogenital examination and clinical assessment. The children, ages 3 to 17 years, had all been referred to an inpatient hospital unit specializing in the assessment of child abuse and neglect. Children were partitioned into three groups: (1) the abuse group that included children who were physically abused, sexually abused, or both; (2) the neglect group that included neglected children and children whose parent had a documented addiction but where there was no indication of abuse; and (3) a nonabused group consisting of children who had been referred to the clinic but where claims of abuse or neglect were not substantiated. Children were administered a series of standard tests (including scales measuring dissociation, memory, and general psychological functioning), measures of stress, and a questionnaire concerning memory for the psychological consultation, including a photo identification task concerning the clinician who conducted the interview. Of particular interest were the children's responses to a questionnaire designed specifically to examine suggestibility in the context of the child's anogenital examination. This contained questions about events that happened (e.g., "Was there a nurse in the doctor's room with you?") as well as misleading questions (e.g., "The nurse took her clothes off, didn't she?").

The results showed the typical age effects in memory, where older children remembered more than younger children and younger children were more susceptible to misleading suggestions than were older children. Of particular importance, maltreated children were no more likely than

nonmaltreated children to confuse details about the medical examination. In other words, maltreated children were no more susceptible to suggestion than nonmaltreated control children.

Although maltreatment may not affect children's ability to correctly remember a medical examination or their ability to resist suggestions about the examination, they may be more susceptible to false memories, particularly those that are relatively automatically generated. In particular, if stress and maltreatment result in lowered cognitive inhibition (e.g., it is more difficult to "screen" intrusive memories or selectively attend to only certain aspects of a stimulus display), then maltreated children may be more susceptible to falsely remembering strong semantic associations when memorizing lists of interrelated concepts. Previous research with nonmaltreated children has shown that, unlike suggestibility effects, false memories such as the ones just described (i.e., those obtained using the Deese-Roediger-McDermott or DRM procedure) increase rather than decrease with age in childhood (for a review, see Brainerd & Reyna, 2005). This is because, although such false memories occur relatively automatically, they do depend on children's being able to extract the meaning of not only each individual concept, but also the common meaning across all of the list members. For example, upon hearing (and trying to remember) the list *bed, rest, awake, tired, dream, wake, snooze, blanket, doze, slumber, snore, nap*, older children are more likely to falsely remember *sleep* than younger children.

To see whether maltreated children were more (or less) susceptible to these types of false memories, Howe et al. (2004) examined three groups of children's performance on the DRM task. Specifically, 60 middle-SES children (the children most frequently sampled when studying memory development and false memories in particular), 48 maltreated low-SES children (all of whom had documented physical, sexual, or emotional abuse or were neglected), and 51 nonmaltreated low-SES comparison children (none of whom were abused or neglected) ages 5 to 12 years studied a series of DRM lists. Recall measures were taken following the presentation of each list and a final recognition test was administered after all of the lists had been presented.

The results showed that all of the children exhibited age increases in both true and false memories, consistent with previous research, and that these patterns were the same regardless of maltreatment status. That is, both maltreated and nonmaltreated children exhibited false memories, and the number of false memories increased with age at the same rate. The only differences that emerged were associ-

ated with SES. That is, consistent with prior studies, low-SES children exhibited poorer overall performance (lower true and false memories) than did middle-SES children.

To summarize, there is considerable reason to believe that maltreated (abused and neglected) children's basic memory processes should be adversely affected if for no other reason than the chronic stress such children have experienced. However, like the conclusion concerning similar subversive effects on neural development, particularly neural developments relevant to memory performance, empirical findings to date do not substantiate such claims. Although admittedly few studies have been published and there are clearly other basic memory processes that need to be examined, those that have been conducted do not reveal differences in basic memory performance between maltreated children and demographically similar nonmaltreated control children.

Perhaps these differences are more apt to show up in maltreated children's recollections of traumatic experiences themselves. Although we have already seen that children tend to be reasonably accurate at remembering traumatic experiences, due perhaps to their distinctiveness (Howe, *in press*), there exists a strong theoretical rationale for the belief that these memories, indeed all of autobiographical memory, may be fundamentally different in children who have been maltreated compared to those who have not (Foa & Rothbaum, 1998; Terr, 1988). We examine this belief next in the context of research on children's (maltreated and nonmaltreated) autobiographical memory.

AUTOBIOGRAPHICAL MEMORY

The stress and trauma of child maltreatment (acute or chronic) can be associated with subsequent psychiatric impairment (MacMillan et al., 2001). In particular, child maltreatment is a risk factor for Major Depressive Disorders (Heim & Nemeroff, 2001) and PTSD (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). The interaction of individual differences characteristics in stress reactivity, cognitive as well as psychobiological, and child maltreatment are complex and lead to considerable variation in predicting which children will come to have psychopathologies (Delahanty, Nugent, Christopher, & Walsh, 2005; Shea, Walsh, MacMillan, & Steiner, 2005). In fact, diversity in process and outcome is a hallmark of a developmental psychopathology perspective (Cicchetti & Rogosch, 1996). These concepts are important to consider when examining memory in victims of trauma. Rather than focusing on main effect models that look broadly at the effects of

trauma on memory, it is necessary to recognize that not all trauma victims are affected similarly (Cicchetti, 2002; Cicchetti & Toth, 1995). The principle of multifinality suggests that similar experiences of trauma may not affect memory in the same way in different individuals. Thus, for example, it is unlikely that all physically or sexually abused children will evidence similar memory changes. This principle is also useful in addressing seemingly discrepant findings in the literature regarding enhanced versus impaired memory in traumatized populations. Conversely, equifinality suggests that there are multiple pathways to the same outcome. Accordingly, various types of traumatic experiences may eventuate in similar effects on memory.

Despite diversity in process and outcome with respect to the emergence of psychopathology, there are some important implications for memory functioning when these pathologies are a consequence of child maltreatment. In this section, we concentrate on those consequences that are associated with autobiographical memory.

Autobiographical memory begins as early as 18 to 24 months of age (see Howe, 2000, 2004a; Howe & Courage, 1993, 1997; Howe, Courage, & Edison, 2003). As noted in trace-integrity theory, this time corresponds to the point at which children acquire a cognitive sense of self, an important ingredient to organizing memories as autobiographical. That is, although as we have already noted that children have both implicit and explicit memory from very early in life, such memories are fragmentary and somewhat disorganized and are not well retained over time. With the advent of the cognitive self, such memories become organized not just as events but as events that happened to "me." Like all other advances in early memory development, information is better retained, becoming more durable, as it becomes better organized. Once children can use the cognitive self to organize events, autobiographical memory emerges and children's memories of events that happened to them become more stable and durable.

This theory not only is logically appealing but also has received empirical support (see Howe, 2004a; Howe et al., 2003). An interesting feature of this theory is that the onset of the cognitive self, and hence autobiographical memory, appears to be controlled more by maturational factors than by environmental factors. For example, infants who have delayed maturation (e.g., due to Down syndrome, familial mental retardation, Autism) show marked delays in the onset of the cognitive self (Cicchetti, 1991; Hill & Tomlin, 1981; Loveland, 1987, 1993; Mans, Cicchetti, & Sroufe, 1978; Schneider-Rosen & Cicchetti, 1984, 1991; Spiker & Ricks, 1984). These children do acquire a cognitive self if and when they achieve a mental age comparable to that of

nondelayed infants who do have a cognitive sense of self. Other recent data have shown a link between the onset of the cognitive self and constitutional factors, such as stress reactivity and temperament (DiBiase & Lewis, 1997; Lewis & Ramsay, 1997). DiBiase and Lewis found that infants with a difficult temperament at 5 months of age were more likely to show earlier acquisition of the cognitive self than were infants with an easy temperament. Lewis and Ramsay found that children with higher stress reactivity (measured in terms of cortisol levels and behavioral responses to inoculations at 2, 4, 6, and 18 months) also had earlier onset of the cognitive self than did those with lower stress reactivity. In contrast, Lewis and Brooks-Gunn (1979) have shown that the onset of the cognitive self is not related to a child's sex, maternal education, family SES, birth order, or number of siblings. Likewise, maltreated infants whose aberrant caretaking environments are associated with delays or deviations in emotional development as it relates to the self are not delayed in the onset of the cognitive self (Cicchetti, 1991; Cicchetti & Beeghly, 1987; Schneider-Rosen & Cicchetti, 1984, 1991), although they do exhibit a more negative reaction to their mirror image (Cicchetti, Beeghly, Carlson, & Toth, 1990; Schneider-Rosen & Cicchetti, 1984, 1991). Thus, the onset of the cognitive self, the critical achievement necessary to kick-start autobiographical memory, is linked more to maturation-constitutional factors than to social-experiential factors. That is, the emergence of the cognitive self and autobiographical memory is associated with maturational achievements and does not appear to be influenced by variations in social or child-care experiences in any obvious way.

Autobiographical memory is, of course, memory for our personal history. When asked to generate detailed personal memories for events, most people can generate fairly specific responses. For example, when a child (or an adult) is presented with the cue word *holiday*, he or she might respond with a fairly specific accounting of a trip to Disney World in Florida (e.g., Hammond & Fivush, 1991). The same cannot be said for people suffering from depression. Such individuals tend to provide an overly general response, such as "I remember enjoying holidays as a child," to autobiographical memory cues. This effect was first discovered in suicidal individuals (J. M. G. Williams & Broadbent, 1986; J. M. G. Williams & Dritschel, 1988) and has subsequently been replicated in other populations of depressed individuals (Brittlebank, Scott, Williams, & Ferrier, 1993; Croll & Bryant, 2000; Dalgleish, Spinks, Yiend, & Kuyken, 2001; Goddard, Dritschel, & Burton, 1996; Henderson, Hargreaves, Gregory, & Williams, 2002;

Kuyken & Dalgleish, 1995; Moore, Watts, & Williams, 1988; Puffet, Jehin-Marchot, Timsit-Berthier, & Timsit, 1991; Wessel, Meeren, Peeters, Arntz, & Merckelbach, 2001; J. M. G. Williams & Scott, 1988), those suffering from Bipolar Disorder (Scott, Stanton, Garland, & Ferrier, 2000), postpsychotic depression (Iqbal, Birchwood, Hemsley, Jackson, & Morris, 2004), adolescent mood disturbances (Swales, Williams, & Wood, 2001), and individuals remitted from Major Depression (Mackinger, Pachinger, Leibetseder, & Fartacek, 2000). Overgenerality of autobiographical memory responses has been found in other clinical populations, including persons suffering from PTSD (McNally, Lasko, Maclin, & Pitman, 1995; McNally, Litz, Prassas, Shin, & Weathers, 1994), Acute Stress Disorder (Harvey, Bryant, & Dang, 1998), Borderline Personality Disorder (Jones et al., 1999; Startup et al., 2001), Obsessive-Compulsive Disorder with comorbid depression (Wilhelm, McNally, Baer, & Florin, 1997), and persecutory delusional patients (Kaney, Bowen-Jones, & Bentall, 1999). These populations all exhibit (or exhibited) significant levels of depression, a history of trauma (particularly childhood trauma), or both. Interestingly, populations that do not have these characteristics do not tend to recall overgeneral autobiographical memories. This latter group includes populations suffering from Seasonal Affective Disorder (Dalgleish et al., 2001), Obsessive-Compulsive Disorder without comorbid depression (Wilhelm et al., 1997), and Generalized Anxiety Disorder (Burke & Mathews, 1992; Wessel et al., 2001), except for those associated with trauma giving rise to PTSD or Acute Stress Disorder.

A variety of explanations have been proposed for why overgeneral retrieval of autobiographical memories occurs in depressed or traumatized populations but not other clinical groups. Although some theories focus on the neurobiological effects of stress, the majority have to do more with cognitive explanations of changes in retrieval patterns than with neurobiologically based problems that necessarily affect the encoding and storage of information. Specifically, J. M. G. Williams (1996) has suggested that autobiographical memory is organized hierarchically (as in Conway & Pleydell-Pearce, 2000). In this model, there are two types of hierarchies in which events are stored and organized: *general categories*, in which information relating to events, people, activities, and places are stored, and *extended time periods*, in which information relating to different life periods, or periods lasting longer than a day, are stored. Within each hierarchy, more specific details are nested. Because information is organized in this top-down fashion, and because retrieval proceeds in a top-down manner, re-

trieval can be aborted at the highest level before specific information is accessed, leading to overgeneral or generic autobiographical recall. Ending a search prematurely in the general categories hierarchy leads to categoric overgeneral memory, in which participants report a summary of several episodes sharing common features (e.g., “I like theme parks”), whereas ending a search prematurely in the extended time period category leads to an extended overgeneral memory that summarizes several episodes from a common time period (e.g., “I enjoyed holidays as a child”). As it turns out, not only are depressed individuals more likely than nondepressed to produce generic memories than specific ones, but they are also more likely to produce categoric overgeneral recall than extended overgeneral memory, whereas the different generic responses when given by nondepressed individuals are equally common (J. M. G. Williams & Dritschel, 1992).

J. M. G. Williams (1996) attempted to link this model to an early sociolinguistic approach to autobiographical memory in childhood (K. Nelson & Gruendel, 1981) in which children were said to first represent and retrieve events generically.¹ Williams hypothesized that stressful experiences during childhood might have led depressed patients to become “arrested” in their generic retrieval of experiences. That is, they adopt a generic retrieval strategy to avoid specifics of past events and hence reduce the negative affect associated with them.

What aspects of a person’s history cause him or her to adopt a retrieval style that stops searching for specific memories and reports only generic information? Studies that have compared prior trauma and depression provide mixed results. First, as we have already indicated, numerous studies (listed earlier) have found that overgeneral autobiographical memories are correlated with depression.

¹It is now known that children’s event representations, like that of other domains of cognitive functioning, are represented quite specifically in memory and that memory development proceeds from specific, verbatim, contextually driven representations to more general, generic, gist-like representations (Brainerd & Reyna, 2005; Howe, 2000; Mandler, 2004). As well, as we have already described in this chapter, it is also known that even young children’s autobiographical memories contain very specific, verbatim details of their experience and are not represented generically (also see Howe, 2000). Of course, although the developmental arrest component of this model is not supported in theory or data, Williams’s point that people in some clinical populations report only generic rather than specific autobiographical information is still seen as feasible by some in the clinical literature today.

However, what is not clear is whether these effects represent true retrieval effects or simply a more general reluctance to report retrieved memories. That is, specific memories may have been retrieved, but depressed patients are simply less likely to report them to an interviewer than are nondepressed individuals. This is consistent with the finding that depressed individuals exhibit global cognitive and memory deficits due to lapses in attention and motivation (Burt, Zembar, & Niederehe, 1995). Although a promising idea, Wessel, Merckelbach, and Dekkers (2002) reported no such association between standardized measures of memory performance and overgeneral autobiographical memory. A further complication, and one that may suggest that overgeneral memory is not simply a reporting issue, are the findings that depressed individuals do produce specific memories as well as overgeneral ones and sometimes produce more specific memories to negatively valenced cues, sometimes produce more specific memories to positively valenced cues, and sometimes there is no difference between positive and negative cues (see Dalgleish et al., 2003).

The view that overgeneral memory may be the result of trauma, particularly trauma in childhood, is supported by Kuyken and Brewin’s (1995) reanalysis of their data set (reported in Dalgleish et al., 2003), in which more overgeneral memories were produced by a clinical sample of individuals who reported having been abused than by those not reporting abuse, even when depressed mood was controlled. The finding that self-reported abuse is linked to overgeneral memory has been replicated in a nonclinical community sample of abuse victims (Henderson et al., 2002). Taken together, these results suggest that self-reported abuse, not depression, may be responsible for overgeneral autobiographical memories. This is consistent with J. M. G. Williams’s (1996) suggestion that exposure to psychological trauma in childhood perturbs the normal development of autobiographical memory (for negative experiences primarily, but may also affect recall of positive experiences) and that children learn a specific retrieval style that minimizes recall of specific experiences. Unfortunately, other researchers have not found a similar link between childhood trauma (self-reported or verified) and overgeneral memory. For example, Wessel et al. (2001) found no relationship between early abuse and overgeneral memory but did find one between depression and overgenerality. Similarly, Wessel et al. (2002) found no relationship between overgeneral memory and childhood trauma but did find an association between depression and overgenerality.

One reason for these discrepant findings concerning the role of abuse may be that the participants in the different studies suffered from varying severities of abuse. That is, studies that have shown a link between abuse and overgeneral memory (Henderson et al., 2002; Kuyken & Brewin, 1995) have differed from those that have not found this link (Wessel et al., 2001) on a number of dimensions, including severity of abuse and/or the presence/absence of abuse. Although the clinical group in the Wessel et al. (2002) study had been interned in Japanese concentration camps during World War II as children and were no doubt exposed to traumatic events at that time, it is not clear what the overall level of trauma exposure was during the internment. It may be, then, that the latter studies did not evince sufficient levels of abuse to detect a relationship with overgeneral memory. Indeed, when a clinical sample is selected such that levels of reported abuse are likely elevated relative to healthy controls, and who do not suffer from mood disorders, there exists a clear association between abuse and overgeneral memory (Dalgleish et al., 2003). Of course, the limitation with these studies is that the association is between overgeneral autobiographical memory and self-reported abuse and not abuse that has been independently corroborated.

It may be that individuals who have been abused in childhood or those who are depressed exhibit overgeneral memory because they may have something in common; that is, traumatic experiences such as physical and sexual abuse in childhood are often associated with depression in both children and adults (Allen & Tarnowski, 1989; Andrews, Valentine, & Valentine, 1995; Bemporad & Romano, 1992; Bifulco, Brown, & Harris, 1994; Carlin et al., 1994; Cicchetti & Rogosch, 2001; Downey, Feldman, Khuri, & Friedman, 1994; Fox & Gilbert, 1994; Kazdin, Moser, Colbus, & Bell, 1985; Kessler & Magee, 1994; Kuyken & Brewin, 1994, 1995; Sternberg et al., 1993; Stone, 1993; Straus & Kantor, 1994; Toth, Manly, & Cicchetti, 1992). This is consistent with J. M. G. Williams's (1996) idea that early traumatic experience leads to a failure to reduce retrieval inhibition in autobiographical memory. That is, because specific emotional information associated with traumatic events is too painful to reexperience, it is defended against by stopping the retrieval process at the overgeneral level. In the only study to examine these effects in traumatized children, Orbach, Lamb, Sternberg, Williams, and Dawud-Noursi (2001) found that children who had been exposed to family violence produced overgeneral autobiographical memories but only for that subsample who was comorbid for depression. Thus, for children, traumatic experiences alone may not be sufficient for the develop-

ment of overgeneral autobiographical recall. Rather, these traumatic experiences must be accompanied by depression.

Somewhat problematic for J. M. G. Williams's (1996) approach is that the developmental sequence for memory is incorrect. As reviewed earlier, memory development from infancy onward (including autobiographical memory) proceeds from remembering highly specific, contextually bound, verbatim information to learning about more general, categorizable gist-like meanings (Brainerd & Reyna, 2005; Howe, 2000; Rovee-Collier et al., 2001). Thus, we do not proceed from the general to the more specific but go from the specific to the more general (also see note 1). Three additional facts are at odds with Williams's account: (1) Depressed and traumatized individuals do remember specific episodes, not just generic information; in fact, the percentage of memories recalled that are specific always exceeds 50% and often exceeds 75% across studies (see Dalgleish et al., 2003), suggesting that lapses into overgeneral retrieval are the exception rather than the rule; (2) when depressed individuals recall specific information, it is more likely when they are given negative cues than positive cues; and (3) individuals with PTSD tend to have intrusive, specific, and very detailed autobiographical recollections of the event related to PTSD (although there may be a difference between involuntary and voluntary autobiographical recall). In fact, concerning this last point, the rate of memory intrusions tends to be highly correlated with overgenerality in autobiographical recall (Brewin, Reynolds, & Tata, 1999; Wessel et al., 2002). Perhaps this association emerges because some individuals use a repressive coping style to avoid consciously ruminating about traumatic memories, increasing the likelihood that they appear as intrusive recollections. Whatever the case may be, it is clear that an alternative theoretical framework is necessary to accommodate the empirical findings.

In summary, what this review has shown is that similar to more basic neurological and memory processes discussed earlier, although there is good reason to suspect that autobiographical memory processes may be perturbed in the presence of childhood maltreatment and the ensuing psychopathology, the empirical evidence is not consistent with that viewpoint. First, there appear to be no differences in the age of onset of autobiographical memory unless a maturational delay exists (e.g., due to Down syndrome, Autism). Second, although childhood trauma and maltreatment have been linked to an overgeneral reporting bias of autobiographical memories, it is not clear that these effects are related to maltreatment per se or to the comorbidity factors such as depression. Indeed, it is not clear that these effects are memory effects at all and are not simply a more

general and global characteristic of depression in which there is frequently a cognitive bias affecting the motivation to participate in tasks or to report memories of experiences. Before we can be certain, considerable research will be needed to sort through these different issues and determine whether changes in autobiographical memory occur as a result of maltreatment or comorbidity factors, and if so, whether such overgeneral reporting is simply a motivational issue consistent with other biases associated with depression or is really a memory retrieval phenomenon.

CONCLUSION AND FUTURE DIRECTIONS

We began this chapter by asking how stress, particularly the chronic stress associated with child maltreatment, affects the development of children's basic memory processes as well as how it affects children's recollection of the stressful and traumatic experiences themselves. Although there are sound theoretical reasons to believe that stress may affect basic memory processes and memory for traumatic experiences (e.g., enhanced consolidation and storage, inhibition of retrieval), the data in hand suggest otherwise. What this review has shown is that the experience of trauma, acute or chronic, does not exert any special effects on memory that fundamentally change the operation of memory from that observed in nontraumatized populations. With that said, however, we want to underscore the fact that research in this area is still in its infancy. Because of the paucity of work in this area, we use the remainder of this chapter to highlight future directions that need to be pursued in order to have confidence that memory operates similarly in traumatized and nontraumatized individuals.

First, and perhaps foremost, we want to emphasize the importance of conducting investigations with individuals who have experienced trauma rather than trying to extrapolate from studies conducted with normal populations or from analogue studies. This recommendation is consistent with developmental psychopathology's commitment to examining atypical as well as normal populations. Unfortunately, historically much of the work on trauma and memory has been conducted with normal populations involved in simulated analogue studies. For example, in investigations of eyewitness testimony, Yuille and Cutshall (1986) reported that between 1974 and 1982, 92% of investigations purporting to examine eyewitness testimony involved college students participating in simulation studies. Much of the early work on false and suggested memories in

children similarly involved simulated studies with normative groups of children (Ceci & Bruck, 1995). Although these studies provide a valuable starting point for examining complex issues, they cannot be viewed as definitive or as the end point. Rather, such studies provide building blocks on which investigations with actual victims of trauma can be initiated. Only when a sufficient body of studies cohere can we truly have confidence about how trauma does, or does not, affect memory.

Related to this, the nature of materials utilized to investigate memory needs to be carefully considered. The normative literature on basic memory provides an excellent point for beginning to determine how memory may operate similarly or differently in traumatized children. However, the fact that memory for standard lists of words utilized with normative populations is not affected by trauma does not mean that memory for emotionally laden words will operate similarly (Rieder & Cicchetti, 1989). Therefore, although beginning with standard memory paradigms allows comparisons with a large normative literature to be made, memory for traumatic material also must be investigated. In this regard, investigations of autobiographical memory may be particularly germane. However, to conduct such investigations, accurate information must be available on the actual event that occurred and on what information an individual recalled immediately following the event. The conduct of such investigations is likely to be particularly challenging and to pose logistic as well as ethical challenges. Immediately following an event, an individual may be involved in investigative and/or court proceedings, and interviews could potentially contaminate the accuracy of the recall of the event. Moreover, over time it might prove to be troubling to an individual to be queried about past trauma. Although utilization of court testimony from the victim and witnesses might provide a window into immediate recall, sensitivity in assessing memory over time is needed. Because it is critically important to enhance our knowledge of autobiographical memory in victims of trauma, the design and conduct of investigations in this arena hold much promise for informing our understanding of trauma and memory.

A number of issues exist in the memory and trauma literature that must be addressed if the field is to move forward in attaining a comprehensive understanding of this important area. A major omission in the extant literature on trauma and memory involves the absence of studies of extreme and chronic stress. It may be that in cases of extreme stress, an event is not stored. However, such a conclusion cannot be drawn in the absence of studies with highly stressed individuals.

The presence of co-occurring risk factors in samples of traumatized individuals has also contributed to difficulty in ascertaining exactly what may be operating to affect memory. For example, in populations who have experienced PTSD, the effects of the trauma on memory per se are confounded with issues such as hospitalization, utilization of medication, the provision of psychotherapy, substance use and abuse, and comorbid mental illness (e.g., depression). Sufficiently large samples with improved control over potentially confounding factors must be conducted to better parse the effects of trauma from other factors.

With the advent of neuroimaging technology, new avenues for examining brain structure and functioning in victims of trauma have emerged. Although such technologies are appealing and may help to elucidate how trauma affects the brain, caution also is in order. Technological advances cannot compensate for the absence of sound theory, careful experimental design, meticulous execution of empirical investigations, and rigorous scientific methodology. It is crucial that these conceptual and methodological issues be placed at the forefront of research on neuroimaging and memory in traumatized populations. Otherwise, it will be unclear whether neuroimaging findings reflect genuine differential physiological processes between traumatized and nontraumatized individuals, whether these processes are merely epiphenomena, or whether these physiological differences represent compensatory or adaptive neurobiological changes (Cicchetti, 2002; Curtis & Cicchetti, 2003; Peterson, 2003). As our understanding of basic memory processes increases, the incorporation of studies involving MRI and fMRI is more likely to yield fruitful results. To date, investigations of brain structure and memory processes have rarely been conducted in the same individuals who have experienced trauma. In the future, it is essential that increasing multiple-levels-of-analysis research on memory and brain structure and function be conducted with traumatized populations.

Although we are increasingly accruing knowledge about trauma and memory, clinical, social policy, and legal implications are inherent in how the questions posed in this chapter are answered. Therefore, a significant responsibility exists to build on current knowledge with normative populations and to design increasingly methodologically rigorous and theoretically sophisticated investigations of trauma and memory. For example, understanding how various types of trauma interact with developmental status to affect memory will be critical for suggesting what type of therapeutic intervention to utilize. Because scientific evidence does not support views that memories can be stored in the body preverbally, efforts to help young trauma vic-

tims recall an event that they, in truth, have no knowledge of could prove to be countertherapeutic. Because trauma may actually alter neuronal connections in the brain (Cicchetti, 2002; DeBellis, 2001), therapies that require victims to relive traumatic events might actually consolidate the maladaptive negative neuronal pathways that may be associated with the experience of trauma. The area of “repressed” memory is particularly salient, and much has been written about the perils inherent in therapists’ suggestion of trauma to patients who may not consciously recall (or who may not have experienced) such trauma (Loftus & Ketcham, 1994). Given our current state of knowledge regarding trauma and memory, unless children or adults seek help specifically to address their reactions to trauma, caution in exploring such events is indicated.

In the policy and legal arenas, we are beginning to attain evidence that memory in victims of trauma is certainly no worse than in the general population. Conversely, we also do not have reason to believe that memories of trauma are indelible or somehow enhanced, nor are they protected from reconstructive processes common to most, if not all, memories. Again, however, we urge caution, as the seminal studies that can shed light on these issues remain to be conducted.

In closing, we are embarking on a new era of investigations of trauma and memory that will involve actual victims of trauma and that will utilize both basic memory paradigms and those that are likely to be more emotionally arousing. We are guardedly optimistic that such investigations not only will enhance our understanding of the operation of memory in victims of trauma, but also will assist in refining and enhancing developmental theories of memory.

REFERENCES	671

Traumatic stress is ubiquitous in our society and represents an enormous public health burden (Kessler & Magee, 1993). Psychological traumas are unique in standing at the crossroads of mind, body, psyche, the individual, and society. As such, trauma can be approached from a variety of perspectives, including biological, genetic, psychological, social, philosophical, literary, and artistic. To fully understand the effects of trauma on the individual, one must consider biological consequences of stress, effects on the individual's psychology, spirit, and character, and the impact on the family, community, and culture. Thus, it is necessary to look at traumatic stress from multiple perspectives at the same time.

Some aspects of the trauma response act as mediators or moderators of other outcomes. For example, spirituality or culture may affect Posttraumatic Stress Disorder (PTSD) outcome, and amygdala sensitivity may (theoretically) influence acute anxiety and chronic stress-related disorders like PTSD. Traumatic stress can also lead to a range of mental health outcomes that have been termed

trauma-spectrum disorders (Bremner, 1999, 2002a), including PTSD, depression, dissociation, anxiety, substance abuse, and eating disorders. This multitude of outcomes is an illustration of the principle of multifinality: one cause leading to multiple outcomes (Cicchetti & Rogosch, 1996).

The multiple-layers approach to trauma requires a focus on development. Trauma can lead to a succession of diverse outcomes as the individual moves through childhood and adolescence to adulthood (Feiring & Lewis, 1996). It is also possible that individuals can end up at the same place but travel different paths. As an example, studies of women with depression show that some were abused in childhood and others were not, suggesting that depression may be related to abuse in some individuals, and other factors (e.g., genetics) may contribute to depression in other individuals. Furthermore, in these studies there were important biological differences in the different groups; for example, the abused depressed women had smaller hippocampal volume (Vythilingam et al., 2002) and potentiated cortisol reactions to stress (Heim et al., 2000). This suggests that one can arrive at the final depression end point by two different paths, for example, early abuse or inherent disposition. Emerging evidence shows that these subtypes have different treatment responses; for example, depression due to early abuse responds more to therapy and less to medica-

The work presented in this review was supported by grants from the National Institute of Mental Health (MH56120), the Emory Conte Center for Early Life Stress, and the Department of Veterans Affairs Traumatic Stress from Multiple Levels of Analysis.

tion. Thus, looking at a problem such as traumatic stress from multiple levels has clinical relevance.

Richters and Hinshaw (1999) have argued that the development of the American Psychiatric Association's (APA, 2000) *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)* represented an abduction of psychological distress into the realm of disorder. Psychological symptoms and mental distress were described as manifestations of primary diseases that, by definition, represented underlying dysfunction in the individual (Wakefield, 1999). This viewpoint made sense and explained much of what clinicians were seeing, but like all easy fixes, it had a downside. Although it fit the medical model, where a specific disease is associated with a specific pathogen, and allowed psychiatrists and psychologists to share a common language with medical doctors and claim common cause, there was never an easy fit. First of all, the model never fully described the phenomena. Not everything about patients with psychological complaints can be defined by the single disease model. Because of this, practitioners had to abandon the model in the real world even though they pretended to follow the model to retain the approval of the experts in their own field. Although taught to diagnose a single condition and apply a single remedy, many clinicians treat clusters of symptoms, or respond to patients on a one-to-one basis. Second, psychiatry has never been fully incorporated into the medical fold, perhaps because of the suspicion that the disorders treated by psychiatrists were fundamentally different from physical conditions, or because of qualms about the scientific foundation for the disorders. In fact, whenever the pathophysiological basis of a disorder in the psychiatry realm is nailed down, it is spirited away to the physical side of medicine. Take the case of Parkinson's disease, which only belatedly was discovered to be due to a degeneration of dopamine neurons in the striatum, or epilepsy, found to be due typically to lesions in the hippocampus rather than possession by evil spirits.

The so-called abduction of disorder has had several consequences. First, it does not fully describe all of the phenomena. Rather than reconsider the paradigm, the response to this has been to add more diagnoses, leading to exponential growth in the size of successive editions of the *DSM*. Second, the disease model implies that each disease is unique and does not overlap with other diseases; however, this has never been the case in psychiatry. Third, inherent in the disease model is the idea that every specific disease has a specific treatment, and the education of clinicians in the proper identification of disease would lead to the proper application of medication treatment. Never mind the fact that the treatment is always the same (i.e., selective

serotonin reuptake inhibitors [SSRIs] for all mood and anxiety disorders). Although the *DSM* was developed by psychiatrists, it was marketed by the pharmaceutical industry, for whom the expansion of diagnosis (and therefore treatment) was in their best interest; therefore, if we are to follow the trail of clues to discover who is the source of abduction of disorder in psychiatry, it would have to lead back to that source.

Traumatic stress can also be viewed from the larger philosophical perspective. All behaviors have to have some evolutionary advantage in order to be preserved. The withdrawal and decreased interest in things that occurs after trauma may have had an evolutionary advantage. For example, individuals under constant threat may have withdrawn more, which may have had survival value. Remember, survival was based on ability to live long enough to reproduce the species, not to have a long life span.

The abduction of disorder by psychiatry has led to the current, somewhat silly situation in which clinicians pay lip service to psychiatric diagnosis because they think it is what the experts expect of them, but in reality do whatever they want. In the academic arena, there is an equally absurd situation, where diagnoses are expected to be "pure" and without comorbidity, leading investigators on a silly goose chase to mollify their readership and get their papers published and grants funded. What is worse, some misguided investigators, in the search for a pure disorder, perform studies on patient groups that are so unusual that they have no applicability to the patients who actually present to clinical practice. However, increasingly findings from the biological arena are not supporting the specificity of disorders; this has led some to think about the comorbidity issue as something other than their "problem." In fact, fields such as genetics and brain imaging, which are empirically based, rather than validating the single, discrete disease model, as they are expected to do, may actually open things up to a more rich appreciation of our patients. That is, they may facilitate the multiple-levels-of-analysis approach.

One area of investigation that may turn the whole issue on its head is the emerging field of the relationship between physical health and mental disorders. Studies have shown that stress, PTSD, and depression can increase the risk of several physical disorders, including heart disease, cancer, infection, diabetes, and asthma. In fact, it is increasingly clear that for many patients presenting to their doctors with a range of mental conditions, there are profound lifestyle, spiritual, and traumatic factors that lie behind their diseases. In many cases, those factors are simply ignored. Rather than asking for psychiatry to be medicalized, maybe

we should be asking medicine to be psychiatrized. That may be better in the long run for patients.

In trying to move beyond the gridlock created by the abduction of disorder, it helps to have a perspective on mental disorders that goes beyond the current *DSM* era. This chapter reviews the long history of research in the traumatic stress area of psychiatry and an even longer history of recognition of the effects of traumatic stress in popular culture that predates the *DSM* era. This chapter argues that, to understand the complete effects of traumatic stress, it is necessary to understand the effects of trauma on the individual psyche, in the context of the individual within society, on the brain, individual physiology, and physical health, predisposition, risk factors, and resiliency—in other words, a multiple-levels-of-analysis perspective.

10,000 YEARS OF TRAUMA

Most research in the area of traumatic stress has taken place in the past 20 years, since the establishment of PTSD as a diagnosis in the *DSM* in 1980 (APA, 1980). However, there is a long history of work in the field of traumatic stress, going back to 1830, with the first description of what was called “railway spine” or railway injuries in England. This was a disorder that occurred after train accidents and was described as involving problems with memory, pain in the back, confusion, amnesia, and increased anxiety—many of the symptoms that today we would call PTSD. The etiology of railway spine was felt to be related to contusions of the spine, which were below the ability of pathological diagnosis to detect. A paper in *Lancet* appeared describing railway spine as a disorder of railway injury without physical trauma. This was the first description of an effect on the individual of a psychological trauma in which there was not actually a physical injury. Subsequently, Erichsen (1866/2001) wrote a book on *Railway and Other Injuries of the Spine* describing in detail the effects of railway injuries.

In parallel with developments in England, the first patients with trauma-related disorders were being recognized in Germany. The German psychiatrist Oppenheim (2001) first described traumatic neurosis, in which a traumatic event leads to long-term symptoms. Oppenheim said that psychological stress or extreme shock could lead to long-term changes in physiology that were unrelated to an actual physical injury, but actually caused changes in physiology in the brain.

With the advent of the First World War in Germany, Italy, and England, shell shock was first described, in which people would forget their name or who they were or where they were on the battlefield. Shell shock was felt to be caused by the shock of exploding shells. However, psychiatrists soon realized that shell shock could occur even when soldiers were far from an exploding shell. This led to the idea that shell shock might be related to psychological trauma.

Things changed in psychiatry at that time as Freud’s (1995) view of the psychoneuroses gained predominance. With Freud, there was more of an emphasis on the unconscious and fantasy, and the idea of traumatic neurosis lost favor. In addition, there was an emphasis on keeping soldiers on the battlefield, and psychiatrists were discouraged from providing diagnoses that explained soldiers’ inability to perform on the battlefield. This added to the demise of traumatic neurosis. In the middle part of the twentieth century, psychoanalysis dominated in the United States and there was no trauma-specific diagnosis such as PTSD.

The rise of biological psychiatry in the United States laid the foundations for examining the physical role in the development of symptoms whose etiology is emotional trauma. Initially, the biological psychiatrists focused on Schizophrenia as being a “real” disorder and left the neuroses to the psychoanalysts. However, with *DSM-III* (1980) the neuroses were written out of the psychiatric nomenclature and replaced with a plethora of specific mood and anxiety disorders. The veterans returning from the Vietnam War in the 1970s became a potent political group that lobbied for recognition. This led to the description of a Vietnam War syndrome that captured the suffering of many veterans related to their war-time experiences. Debate went back and forth about whether war-time experiences caused the veterans’ symptoms or preexisting personality problems were responsible. At the core of the debate was whether war caused mental disorders, with the implications for whether the government should be responsible for the disabilities of veterans. The development of rating scales allowed researchers to show a correlation between trauma severity and symptom outcomes (Keane, Caddell, & Taylor, 1988; Keane, Wolfe, & Taylor, 1987), leading to a total triumph of the war etiology group. This led to the inclusion of PTSD in the *DSM-III* in 1980, emphasizing for the first time in the twentieth century the central role of trauma.

PTSD has always been unique in requiring a trauma exposure for the diagnosis, even though other disorders, such as the dissociative disorders, are just as strongly linked to trauma exposure. This requirement for trauma exposure,

called Criteria A in *DSM-III*, involved exposure to an event beyond the range of normal human experience. However it quickly became apparent that many traumas are fairly common, so in *DSM-IV*, there is the requirement of exposure to a threat to life, to self, or significant other accompanied by intense fear, horror, or helplessness (Saigh & Bremner, 1999). Traumatic stress so defined affects more than half of the U.S. population.

The creation of the diagnosis allowed biological research on PTSD and also controlled trials of treatment with medication or psychotherapy. The acknowledgment of PTSD in veterans led to research on child sexual trauma in the United States.

Throughout all of this history there is a pattern of multiple threads moving parallel to one another but never really connecting and informing one another. For instance, the false memory thread developed oblivious to the biological correlates of the PTSD thread, even though they had information that was mutually informative. Sometimes this is driven by institutional or disciplinary chauvinism (e.g., who are the “real scientists” or the “real researchers,” or alternatively, who is doing “relevant” research). Like all forms of prejudice, this type of thinking helps to keep things orderly and risk-free but limits the capacity to think outside the box. An analysis from multiple levels implicitly crosses these boundaries and offers a different perspective, moving toward the goalposts that the National Institutes of Health “road map” has been nudging us toward.

THE FAUSTIAN BARGAIN OF THE DIAGNOSTIC AND STATISTICAL MANUAL III

Although the development of the *DSM-III* resulted in greater research and recognition in the field of traumatic stress, in some sense it has been a Faustian bargain. To throw out the old psychoanalytic system, the Faustian bargain of *DSM-III* was to allow no theoretical or etiological constructs to come into play in the development of the individual psychiatric syndromes. Although *DSM-III* provided crisper definitions of mental disorders, it also sold the concept of multiple stand-alone mental disorders, defined only by the face value of their presenting symptoms. In cases where the same symptoms were identical between disorders, they were simply reworded to appear unique to the disorder. For example, rather than state that veterans could reexperience a traumatic event in a dissociated state with elements of derealization, depersonalization, and amnesia, much as a childhood abuse victim does, it was stated that

veterans experienced “flashbacks,” which were felt to be unique to the veteran experience. Implicit in this was a desire to fight for the diagnosis of the veteran with PTSD as being distinct from other disorders, such as dissociative disorders, that could drag the whole enterprise down with it. The result was a poor understanding by clinicians of the symptoms, their etiology, and phenomenology. Needless to say, the drug companies had a field day with this plethora of diagnoses, as it boosted sales of their antidepressants, and hurried to train clinicians in the new diagnoses as well as, of course, the new treatments to be applied.

In an editorial (Bremner, 1999) and later in *Does Stress Damage the Brain?* (Bremner, 2002a), I argued for the concept of trauma-spectrum psychiatric disorders, or a grouping of disorders with a common link to trauma. In this model, stress acting against a background of genetic predisposition and a history of prior stressors (which we know increases the risk for psychopathology with retraumatization) leads to a number of psychiatric disorders, including PTSD. There is overlap between symptoms of PTSD, depression, dissociation, Borderline Personality Disorder, and other stress-related disorders. Symptoms of flashbacks seen in PTSD are really dissociative phenomena. Amnesia and identity disturbance are seen in personality disorders, PTSD, and dissociative disorders. I advocated for disorders related to trauma being included in a separate diagnostic category. PTSD is an anxiety disorder, in a separate category from dissociative disorders, although it shares in common with dissociative disorders the trauma ideology and has less in common with such disorders as Obsessive-Compulsive Disorder. According to this argument, there are not separate distinct disorders, but instead a single spectrum of disorders that have been improperly categorized as distinct by our current diagnostic schema.

TRAUMA AND THE SELF

The development of the *DSM* represented an embrace of the one disease, and by implication, one etiology model. In the case of psychological trauma, the one disease was PTSD and the etiology was the trauma. Trauma was construed as something like a bacterium that caused an infection and could be treated by a single drug. This represented a medicalization of trauma. However, it ignored the profound effect that traumatic experiences have on the self, character, psyche, and the individual in society and culture.

Psychological trauma can lead to more than the development of specific psychiatric disorders: It can have a major

impact on our total way of viewing the world and ourselves that transcends a specific disorder. We all have an illusion that the world is a safe and just place. That's because we need such an illusion to survive. The world would be a terrible place if we could foresee the future, if we knew everything that was going to happen to us. It is our ignorance of the true nature of the world that keeps us sane. Traumatized patients with the diagnosis of PTSD often do not see the world as a safe place. A woman who has a child snatched from her arms by a kidnapper will forever after live with the knowledge that anyone at any time could suddenly take another of her children from her. Someone who was taken hostage will never feel safe walking down a city street.

Not only individuals but entire nations and cultures can be traumatized as well. We saw that play out on a national scale with 9/11. Studies in the aftermath of 9/11 demonstrated that the amount of time spent watching TV was correlated with poor mental outcomes. In other words, the media of this country had become the agent of traumatization. The media also extended the reach of the trauma far beyond the immediate vicinity of Manhattan. More recently, we have had the worldwide traumatization of the tsunami in the Indian Ocean.

By its very nature, trauma extends beyond the individual and takes political and societal dimensions. Terrorists recognize the political potential of psychological trauma and use it well. Terrorists target aspects of life that we take for granted, such as the public mail system and public transportation, in an effort to jolt us out of a sense of safety and security. By doing things like sending anthrax in the mail, terrorists create a sense of national fear, where everyone is hanging on every piece of news, trying to understand what is happening and to protect themselves. The anthrax scare effectively created a traumatic event for the entire nation, as every one, to varying degrees, feels the potential threat of receiving infected mail.

GENETIC CONTRIBUTIONS TO TRAUMA-INDUCED PSYCHOPATHOLOGY

When considering the trauma response from multiple levels it is important to assess the role of genetics. Twin pair studies offer an ideal method for examining the contribution of genetic and environmental factors to variables such as the trauma response. By definition, monozygotic (identical) twins share the same genetic material, and dizygotic (fraternal) twins share 50% of the same genetic material. In addition, because these twins share the same household, they have shared environmental experiences. Therefore, twins

are similar for all variables except the variable of interest. The Vietnam Era Twin Registry has been used for studies of the relative contribution of genetics and environment to trauma-related psychopathology (Eisen, Neuman, Goldberg, Rice, & True, 1989; Goldberg, True, Eisen, Henderson, & Robinette, 1987; Henderson et al., 1990). The Registry consists of 7,375 male-male twin pairs born between 1939 and 1957 with both brothers having served in the U.S. military during the Vietnam era (Henderson et al., 1990). The Twin Registry categorizes pairings where only one brother was in combat in Vietnam, neither went to Vietnam, and both went to Vietnam (Goldberg et al., 1987). By examining all possible combinations of twins, it is possible to determine the relative role of genetics and environment in the development of trauma-related outcomes such as PTSD. Using these methods, a telephone survey was conducted with 2,090 monozygotic twin pairs with Vietnam era military service; 715 monozygotic twins served in Southeast Asia (SEA) and had a twin who did not serve in SEA. PTSD was found to be strongly associated with military service in SEA, with a nine-fold increase in PTSD in the SEA twins who experienced high levels of combat compared to the non-SEA twin (95% confidence interval, 4.8 to 17.6; Goldberg, True, Eisen, & Henderson, 1990). Other studies found a substantial contribution of genetic factors to PTSD symptomatology, with 13% to 34% of the variance in liability for symptoms in the different PTSD symptom clusters accounted for by genetic factors (Goldberg et al., 1990; True et al., 1993). These findings show that there is a combined genetic and environmental (i.e., stress) contribution to PTSD. The exact mechanism by which genetics confers an increased risk for PTSD is not known.

Genetic factors can confer risk for trauma-related psychopathology in several ways. One study found that individuals with a genetic polymorphism for the short form of the serotonin transporter were at risk for depression if they were exposed to a major stressor (Caspi et al., 2003). Thus, in two individuals exposed to the same stress, those with the short form of the serotonin transporter will be at increased risk. Studies have shown that traumatic stress is associated with an increased risk of depression. In addition, some individuals may actually be at increased risk for being exposed to traumatic stressors, which underlies their increased risk of depression (Kendler, Thornton, & Gardner, 2000), rather than some genetic alteration.

Looking at the problem of PTSD from multiple levels of analysis can involve assessing how genetic factors act in the brain to confer risk for PTSD. Some studies have found evidence for lower IQ before trauma exposure predicting risk for PTSD (Macklin et al., 1998; McNally & Shin, 1995);

other studies found smaller hippocampal volume in twins whose brothers developed PTSD secondary to combat exposure (Gilbertson et al., 2002). Genetic contributions to smaller hippocampal volume in PTSD could be mediated either by smaller hippocampal volume at birth (Pitman, 2001) and/or increasing vulnerability for stress exposure or increased responsiveness to stressors (Kendler et al., 2000). Our own preliminary data in twins show a 9% reduction in hippocampal volume in twins with combat-related PTSD relative to their non-combat-exposed twin brothers; these results are consistent with a combined genetic and environmental contribution to smaller hippocampal volume.

NEUROPHYSIOLOGICAL RESPONSES TO TRAUMA

Trauma also has lasting effects on the body and physiological systems (Figure 16.1). Stress circuits, such as the cortisol and norepinephrine systems, and brain regions involved in memory, including the hippocampus, amygdala, and prefrontal cortex, are sensitive to stress (Bremner, 2002b; Bremner & Vermetten, 2001). Changes in these circuits and systems lead to symptoms of PTSD and other stress-re-

lated psychiatric disorders such as depression and dissociative disorders (Bremner, 2002a).

Stress is associated with activation of the hypothalamic-pituitary-adrenal (HPA) axis. Corticotropin-releasing factor (CRF) is released from the hypothalamus, with stimulation of adrenocorticotropic hormone (ACTH) release from the pituitary, resulting in cortisol release from the adrenal gland. This process, in turn, has a negative feedback effect on the HPA axis at the level of the pituitary as well as central brain sites, including the hypothalamus and hippocampus. In addition to its role in activating the HPA axis, CRF acts centrally to mediate fear-related behaviors (Arborelius, Owens, Plotsky, & Nemeroff, 1999) and triggers other neurochemical responses to stress such as the noradrenergic neurotransmitter system via the brain stem's locus coeruleus (Melia & Duman, 1991). Early life stress leads to long-term sensitization of the HPA axis and increases in CRF (Levine, Weiner, & Coe, 1993; Stanton, Gutierrez, & Levine, 1988). Rats deprived of their mother had decreased numbers of glucocorticoid receptors, as measured by binding of the drug dexamethasone, in the hippocampus, hypothalamus, and frontal cortex (Ladd, Owens, & Nemeroff, 1996), increased CRF stress (Coplan et al., 1996; Makino, Smith, & Gold, 1995), and stress-induced glucocorticoid (Plotsky & Meaney, 1993) and ACTH release (Ladd et al., 1996). Stress also results in chronic overactivation of the norepinephrine system, which plays a critical role in the fight-or-flight response (Bremner, Krystal, Southwick, & Charney, 1996a, 1996b).

The hippocampus, a brain area involved in learning and memory, is particularly sensitive to the effects of stress (McEwen et al., 1997; Sapolsky, 1996). Psychosocial stress with associated elevated levels of glucocorticoids results in decreased branching of dendrites, which carry electrical signals to cells, and/or neuronal loss in a region of the hippocampus (Uno, Tarara, Else, Suleman, & Sapolsky, 1989) and a decrease in the regeneration of neurons (Gould, Tanapat, McEwen, Flugge, & Fuchs, 1998) in the hippocampus. High levels of glucocorticoids seen with stress have also been associated with deficits in new learning, in addition to damage to the hippocampus (Diamond, Fleshner, Ingersoll, & Rose, 1996; Lemaire, Koehl, Le Moal, & Abrous, 2000; Luine, Villages, Martinex, & McEwen, 1994). Brain-derived neurotrophic factor (BDNF) is a recently isolated neuropeptide that has important nutritional effects on the hippocampus and other brain regions. Stress results in a reduction in BDNF messenger RNA in the hippocampus, suggesting that stress reduces the brain's ability to grow and thrive. CRF also has a direct effect on the hippocampus in early development (Brunson, Eghbal-Ahmadi,

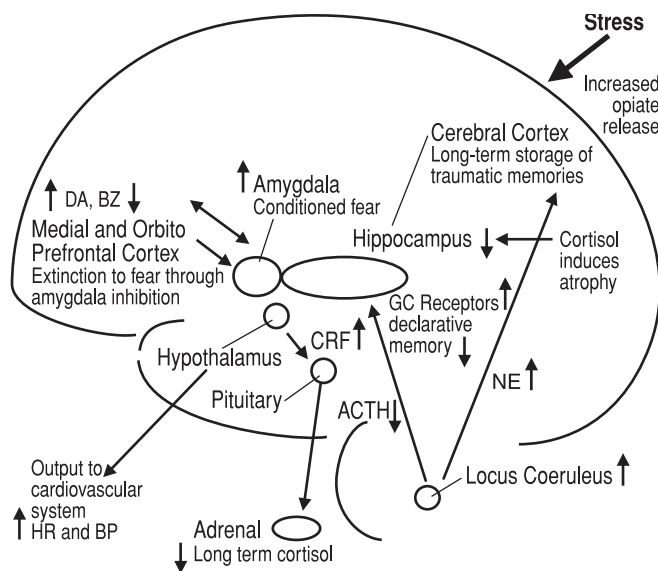

Figure 16.1 Model of how traumatic stress affects the brain. Stress is associated with acute increases in cortisol and norepinephrine. With chronic stress there is dysregulation of these systems, with increased amygdala function and decreased hippocampal and medial prefrontal function. Outputs through the hypothalamus and medial prefrontal cortex increase peripheral sympathetic and cortisol function, increasing the risk of heart disease.

Bender, Chen, & Baram, 2001). In one study, antidepressant drugs and electroconvulsive therapy increased BDNF levels in two regions (CA3 and CA1) of the hippocampus, reversing the effects seen in stress (Nibuya, Morinobu, & Duman, 1995). Serotonin reuptake inhibitors also increase dendritic branching and neurogenesis within the hippocampus (Malberg, Eisch, Nestler, & Duman, 2000). Phenytoin (Dilantin), a medication used to treat epilepsy, inhibits excitatory amino acid transmission and blocks the effects of stress on the hippocampus (Watanabe, Gould, Cameron, Daniels, & McEwen, 1992). These findings have implications for treatment of PTSD and depression and have stimulated clinical trials of these agents to look at their effects on memory and hippocampal volume in PTSD and depression. Thus, there may be potential to treat or perhaps even reverse some of the detrimental effects of child abuse.

The hippocampus demonstrates an unusual capacity for plasticity, the ability of neurons to change and regenerate in response to environmental inputs. In addition to findings noted earlier related to the negative effects of stress on neurogenesis, it has recently been demonstrated that changes in the environment, for example, social enrichment, can modulate generation of neurons in the dentate gyrus of the hippocampus and slow the normal age-related decline in neurogenesis (Kempermann, Kuhn, & Gage, 1998). These findings may have implications for victims of abuse as well as emotional neglect.

An animal model that has been applied to study beneficial early interventions is postnatal handling—the quality of physical contact between a caregiver and an infant. Postnatal handling has important effects on the development of behavioral and endocrine responses to stress. For example, daily handling within the first few weeks of life (picking up rat pups and then returning them to their mother) resulted in increased Type II glucocorticoid receptor binding, which persisted throughout life. This was associated with increased feedback sensitivity to glucocorticoids and reduced glucocorticoid-mediated hippocampal damage in later life (Meaney, Aitken, van Berkel, Bhatnager, & Sapolsky, 1988). These effects appear to be due to a type of “stress inoculation” from the mother’s repeated licking of the handled pups (Liu, Diorio, Day, Francis, & Meaney, 2000). Considered together, these findings suggest that early in the postnatal period there is a naturally occurring brain plasticity in key neural systems that may “program” an organism’s biological response to stressful stimuli.

The medial prefrontal cortex includes the anterior cingulate, orbitofrontal cortex, and ventral prefrontal cortex and is a major target area of the neurotransmitters dopamine and

norepinephrine. The prefrontal cortex has been suggested to play a role in working memory in conjunction with other brain areas, such as the hippocampus. A critical range of dopamine and norepinephrine turnover is necessary for keeping this working memory system active and ready for optimal cognitive functioning (Horger & Roth, 1996), a situation that is impaired in situations of extreme or chronic stress (Arnsten, 2000). The mesofrontal dopaminergic system also plays a role in emotional responses, selective information processing, and coping with the external world (Devinsky, Morrell, & Vogt, 1995; Pani, Porcella, & Gessa, 2000). The medial prefrontal cortex has inhibitory inputs to the amygdala that have been hypothesized to play a role in the extinction of fear responses (Milad & Quirk, 2002; Morgan & LeDoux, 1995). The area of the effects of early stress on mesofrontal dopamine function is not well developed; however, imaging findings from patients with childhood abuse implicate dysfunction of the medial prefrontal cortex.

The medial prefrontal cortex plays a critical role in regulation of peripheral neurohormonal responses to stress (Feldman, Conforti, & Weidenfeld, 1995). In addition to the amygdala and the hypothalamus, portions of the medial prefrontal cortex (infralimbic, ventral prelimbic) project to the nucleus solitarius and nucleus ambiguus in the brain stem, where they regulate heart rate and blood pressure responses to stress. Lesions of the dorsal part of this region (anterior cingulate) resulted in increased heart responses to conditioned stimuli, suggesting that this region decreases heart rate response to stress; lesions in the ventral portion decreased heart response, suggesting that this region increases heart rate response to stress (Fryszak & Neafsey, 1994). Lesions of the medial prefrontal cortex are associated with a blunted cortisol and ACTH response to stress, with no effect on resting cortisol (Diorio, Viau, & Meaney, 1993).

THE NEUROBIOLOGY OF EARLY STRESS IN CHILDREN

The few studies of the effects of early stress on neurobiology conducted in clinical populations of traumatized children have generally been consistent with findings from animal studies. Research with traumatized children has been complicated by issues related to psychiatric diagnosis and assessment of trauma (Cicchetti & Walker, 2001). Some studies have not specifically examined psychiatric diagnosis, whereas others have focused on children with

trauma and depression and still others on children with trauma and PTSD. In our view, the issues of diagnosis are important in this area. Not all children will develop psychopathology following exposure to abuse, and we hypothesize that stress-induced changes in neurobiology that individuals are uniquely susceptible to underlie the development of psychiatric symptoms (Bremner, 2002a; Bremner & Vermetten, 2001).

Studies in adults with a history of early childhood abuse and the diagnosis of PTSD have been consistent with long-term changes in the HPA axis, hippocampal morphology, and hippocampal-based memory function (Bremner & Vermetten, 2001). An increase in cerebrospinal fluid concentrations of CRF was shown in adult patients with combat-related PTSD compared to healthy controls (Baker et al., 1999; Bremner, Licinio, et al., 1997). Consistent with increased levels of CRF, combat-related PTSD patients had a blunted ACTH response to CRF challenge (Smith et al., 1989), although adult women with PTSD showed the opposite response (Rasmusson, Lipschitz, Bremner, Southwick, & Charney, 2001). Some studies (Yehuda, Southwick, Nussbaum, Giller, & Mason, 1991) but not others (Pitman & Orr, 1990) of adults with chronic PTSD found decreased levels of cortisol in 24-hour urines. Other findings in combat-related PTSD include increased suppression of cortisol with low-dose (0.5 mg) dexamethasone (Yehuda et al., 1993) and increased number of glucocorticoid receptors on peripheral lymphocytes (Yehuda, Lowry, Southwick, Mason, & Giller, 1991). Sexually abused girls (in which effects of specific psychiatric diagnosis was not examined) had blunted ACTH response to CRF (DeBellis, Chrousos, et al., 1994), and women with childhood abuse-related PTSD had hypercortisolemia (Lemieux & Coe, 1995). Another study of traumatized children in which the diagnosis of PTSD was established showed increased levels of cortisol measured in 24-hour urines (DeBellis, Baum, et al., 1999). Emotionally neglected children from a Romanian orphanage had elevated cortisol levels over a diurnal period compared to controls (Gunnar, Morison, Chisolm, & Schuder, 2001). Maltreated school-age children with clinical-level internalizing problems such as depression and anxiety had elevated cortisol compared to controls (Cicchetti & Rogosch, 2001). Adult women with a history of childhood abuse showed increased suppression of cortisol with low-dose (0.5 mg) dexamethasone (Stein, Yehuda, Koverola, & Hanna, 1997). In a study of women with PTSD related to early childhood sexual abuse, Bremner and colleagues showed decreased baseline cortisol in the

afternoon (12 to 8 P.M.) based on 24-hour diurnal assessments of plasma cortisol and exaggerated cortisol response to stressors (traumatic stressors; Elzinga, Schmahl, Vermetten, van Dyck, & Bremner, 2002) more than neutral cognitive stressors (Bremner, Vythilingam, Vermetten, Adil, et al., 2002) relative to controls.

Few studies have examined noradrenergic function related to childhood abuse. Studies have found increased noradrenergic function in adults with PTSD (Bremner, Krystal, et al., 1996b). Studies in children with abuse in which diagnosis of PTSD was not established found increased catecholamines in 24-hour urine (including norepinephrine, epinephrine, and dopamine; DeBellis, Lefter, Trickett, & Putnam, 1994). Studies in children with the diagnosis of PTSD are also consistent with elevations in catecholamine (DeBellis, Baum, et al., 1999). These findings are consistent with animal studies showing increased noradrenergic activity following early stress.

Another important outcome of childhood abuse is depression. Hypercortisolemia is a well-replicated finding in a subgroup of patients with depression. Depressed patients also showed increased rates of nonsuppression on the dexamethasone suppression test (consistent with excessive levels of cortisol in the periphery), elevated CRF levels in cerebrospinal fluid (Nemeroff et al., 1984), and blunted ACTH response to CRF challenge (consistent with excessive CRF release; Gold et al., 1986). Findings in adolescents with depression are less clear, with a smaller number of patients exhibiting hypercortisolemia, which may be specific to nighttime cortisol levels (Birmaher et al., 1992; Dahl et al., 1991; Dorn et al., 1996; Kutcher et al., 1991). These discrepant findings may be related to the fact that hypercortisolemia is more common in patients with trauma histories (Hart, Gunnar, & Cicchetti, 1996). Adult women with depression and a history of early childhood abuse had an increased cortisol response to a stressful cognitive challenge relative to controls (Heim et al., 2000) and a blunted ACTH response to CRF challenge (Heim, Newport, Bon-sall, Miller, & Nemeroff, 2001).

Childhood abuse has also been associated with changes in central brain function. Several studies have shown alterations in electroencephalogram (EEG) measures of brain activity in children with a variety of traumas who were not selected for diagnosis compared to healthy children. About half of the children in these studies had a psychiatric diagnosis. Abnormalities were located in the anterior frontal cortex and temporal lobe and were localized to the left hemisphere (Ito et al., 1993; Schiffer, Teicher, & Papanicolaou, 1995).

Studies in adult survivors of childhood abuse have found abnormalities in the hippocampus. Neuropsychological tests of long-term memory function, such as the verbal Selective Reminding Test (vSRT), and percentage of retention during paragraph recall on the Wechsler Memory Scale (WMS) can be used as probes of hippocampal function. Bremner, Randall, Capelli, et al. (1995) found deficits in verbal declarative memory as measured by the WMS and vSRT in patients with childhood physical and sexual abuse in comparison to controls. Deficits in verbal memory in the childhood abuse patients were significantly correlated with severity of childhood sexual abuse.

Based on the animal studies reviewed earlier, there was a rationale to measure hippocampal volume in patients with PTSD and depression. An initial study used magnetic resonance imaging (MRI) volumetric (i.e., size measurement) techniques to show an 8% reduction in hippocampal volume in patients with combat-related PTSD compared to controls (Bremner, Randall, Scott, et al., 1995; Figure 16.2). In a second study comparing 17 patients with PTSD related to early childhood abuse to 17 case-matched controls, there was a 12% reduction in left hippocampal volume ($p < .05$; Bremner, Randall, et al., 1997). Other published studies showed hippocampal volume reduction, for example, in combat-related PTSD (Gurvits et al., 1996) and in women with early sexual abuse, most of whom met criteria for PTSD (Stein, Koverola, Hanna, Torchia, & McClarty, 1997). We recently found a reduction in bilateral hippocampal volume in women with early childhood sexual abuse and PTSD, relative to abused women without PTSD and nonabused non-PTSD women (Bremner, Vythilingam,

Vermetten, Southwick, McGlasha, Nazeer, et al., 2003). In studies of children with abuse-related PTSD, there was a smaller intracranial and cerebral volume, with no reduction in hippocampal volume (Carrion et al., 2001; DeBellis, Keshavan, et al., 1999) and no change in hippocampal volume over a 2-year period (DeBellis, Hall, Boring, Frustaci, & Moritz, 2001). Adults with new-onset PTSD showed no difference in hippocampal volume relative to controls (Bonne et al., 2001). MRI studies in adult depression showed smaller hippocampal volume in adults with depression (Bremner, 2002c). Recently, we found that smaller left hippocampal volume was seen only in women with depression and a history of childhood abuse, but not in depressed women without childhood abuse (Vythilingam et al., 2002). These studies suggest that chronicity of PTSD illness may be a factor determining hippocampal volume reduction. Similarly, chronicity of depression has been associated with degree of hippocampal atrophy.

NEUROIMAGING OF BRAIN FUNCTION IN EARLY TRAUMA

Neuroimaging studies have provided a map for the neural circuitry of early childhood abuse (Bremner, 2002b). The medial prefrontal cortex has been implicated in the stress response. The medial prefrontal cortex in the human consists of several related areas, including the orbitofrontal cortex, anterior cingulate (area 25-subcallosal gyrus, and Area 32), and anterior prefrontal cortex (area 9). This area plays a critical role in extinction of fear (Milad & Quirk, 2002; Morgan & LeDoux, 1995). Human subjects with lesions of the prefrontal cortex showed dysfunction of normal emotions and an inability to relate in social situations that require correct interpretation of the emotional expressions of others (Damasio, Grabowski, Frank, Galaburda, & Damasio, 1994). These findings suggest that dysfunction of the medial prefrontal cortex may play a role in pathological emotions that sometimes follow exposure to extreme stressors such as childhood sexual abuse. Other regions, including the posterior cingulate, parietal and motor cortex, and cerebellum, are functionally related to the anterolateral prefrontal cortex (superior and middle frontal gyri), mediating visuospatial processing that is critical to survival in life-threatening situations. We have hypothesized that the excessive vigilance seen in PTSD is associated with increased demands on brain areas involved in visuospatial aspects of memory function and planning of response to potentially threatening stimuli.

Hippocampal Volume Reduction in PTSD

Figure 16.2 Hippocampal volume in PTSD on a coronal MRI. The hippocampus is visibly smaller in the PTSD patient compared to a normal control.

In a study that followed up on findings of reduced hippocampal volume in abuse-related PTSD, we measured hippocampal function and structure in childhood abuse-related PTSD. Hippocampal function during the performance of hippocampal-based verbal declarative memory tasks was measured using positron emission tomography (PET) and [^{15}O]H $_2$ O (radioactive water that binds in the brain to show change in blood flow) in women with a history of early childhood sexual abuse with and without PTSD. Hippocampal volume was measured with MRI in three subject groups: women with early childhood sexual abuse and PTSD, women with early abuse without PTSD, and women without early abuse or PTSD. A failure of hippocampal activation ($F = 14.94$; $df = 1,20$; $p < .001$) and 16% smaller volume of the hippocampus was seen in women with abuse and PTSD compared to women with abuse without PTSD. Abused PTSD women also had a 19% smaller hippocampal volume relative to women without abuse or PTSD (Bremner, Vythilingam, Vermetten, Southwick, et al., 2002). These results are consistent with the hypothesis that early abuse with associated PTSD results in deficits in hippocampal function and structure, possibly through damage to hippocampal neurons.

Functional neuroimaging studies have been performed in childhood abuse-related PTSD to map out the neural circuitry of abuse-related PTSD (Figure 16.3). These studies are consistent with dysfunction in a network of related brain areas, including the medial prefrontal cortex, hippocampus, and amygdala (Figure 16.4). We measured brain blood flow with PET and [^{15}O]H $_2$ O during exposure to personalized scripts of childhood sexual abuse. Twenty-

two women with a history of childhood sexual abuse underwent injection of [^{15}O]H $_2$ O followed by PET imaging of the brain while listening to neutral and traumatic (personalized childhood sexual abuse events) scripts. Brain blood flow during exposure to traumatic versus neutral scripts was compared between sexually abused women with and without PTSD. Memories of childhood sexual abuse were associated with greater increases in blood flow in portions of the anterior prefrontal cortex (superior and middle frontal gyri-areas 6 and 9), posterior cingulate (area 31), and motor cortex in sexually abused women with PTSD compared to sexually abused women without PTSD. Abuse memories were associated with alterations in blood flow in the medial prefrontal cortex, with decreased blood flow in subcallosal gyrus-area 25 and a failure of activation in anterior cingulate-area 32. There was also decreased blood flow in the right hippocampus, fusiform/inferior temporal gyrus, supramarginal gyrus, and visual association cortex in PTSD relative to non-PTSD women (Bremner, Narayan, et al., 1999). This study replicated findings of decreased function in the medial prefrontal cortex and increased function in the posterior cingulate in combat-related PTSD during exposure to combat-related slides and sounds (Bremner, Staib, et al., 1999; Figure 16.5). Shin et al. (1999) studied 8 women with childhood sexual abuse and PTSD and 8 women with abuse without PTSD using PET during exposure to script-driven imagery of childhood abuse. The authors found blood-flow increases in the orbitofrontal cortex and anterior temporal pole in both groups of subjects, with greater increases in these areas in the PTSD group. PTSD patients showed a relative failure of the anterior cingulate activation compared to controls. The PTSD patients (but not controls) showed decreased blood flow in anteromedial portions of the prefrontal cortex and left inferior frontal gyrus.

These studies have relied on specific traumatic cues to activate personalized traumatic memories of childhood abuse and PTSD symptoms in patients with PTSD. Another method to probe neural circuits in PTSD is to assess neural correlates of retrieval of emotionally valenced declarative memory. In this type of paradigm, instead of using a traditional declarative memory task, such as retrieval of word pairs like “gold-west,” which has been the standard of memory research for several decades, words with emotional valence, such as “stench-fear” are utilized (Bremner et al., 2001). Although there has been relatively little research on retrieval of emotionally valenced words, it is of interest from the standpoint of PTSD as a method for activating neural pathways relevant to trauma and memory. If PTSD patients demonstrate a pattern of brain

Figure 16.3 Replicated findings in PTSD. The most replicated findings related to symptom provocation are decreased medial prefrontal function. Other findings include decreased hippocampal and dorsolateral prefrontal function and increased amygdala function.

**Increased Blood Flow with Fear Acquisition
versus Control in Abuse-Related PTSD**

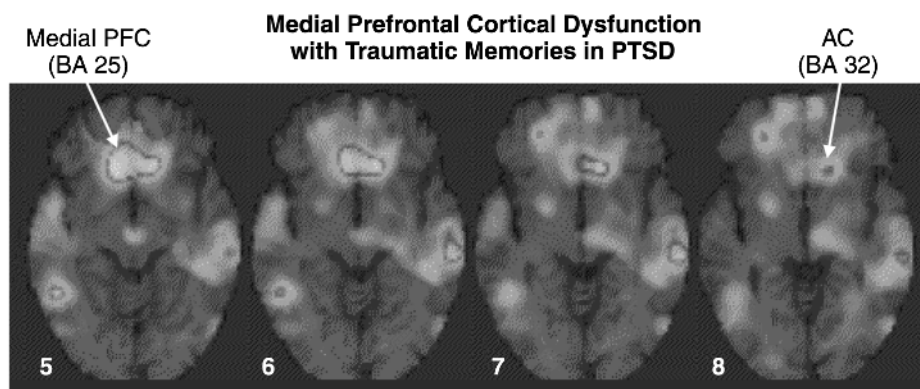

Figure 16.4 Amygdala function in PTSD. With classical fear conditioning (pairing of an unconditioned stimulus [shock] with a conditioned stimulus [seeing a blue square on a screen]), there was increased amygdala activation in PTSD relative to controls, suggesting increased sensitivity of the amygdala in the learning of fear.

activation during retrieval of emotionally valenced declarative memory that is similar to that seen during exposure to other tasks that stimulate brain networks mediating PTSD symptoms, such as exposure to personalized scripts of childhood trauma or exposure to trauma-related pictures and sounds, then that would provide convergent evidence for dysfunction of a specific neural circuit in the processing of emotional memory in PTSD. We recently used PET in the examination of neural correlates of retrieval of emotionally valenced declarative memory in 10 women with a history of childhood sexual abuse and the diagnosis of PTSD and 11 women without abuse or PTSD. We hypothesized that retrieval of emotionally valenced words would result in an altered pattern of brain activation in patients with PTSD similar to that seen in prior studies of exposure to cues of personalized traumatic memories. Specifically, we hypothesized that retrieval of emotionally valenced

words in PTSD relative to non-PTSD subjects would result in decreased blood flow in the medial prefrontal cortex (subcallosal gyrus and other parts of the anterior cingulate), hippocampus, and fusiform gyrus/inferior temporal cortex, with increased blood flow in the posterior cingulate, motor and parietal cortex, and dorsolateral prefrontal cortex. PTSD patients during retrieval of emotionally valenced word pairs showed greater decreases in blood flow in an extensive area that included the orbitofrontal cortex, anterior cingulate, and medial prefrontal cortex (Brodmann's areas 25, 32, 9), left hippocampus, and fusiform gyrus/inferior temporal gyrus, with increased activation in the posterior cingulate, left inferior parietal cortex, left middle frontal gyrus, and visual association and motor cortex. There were no differences in patterns of brain activation during retrieval of neutral word pairs between patients and controls (Bremner, Vythilingam, Vermetten, South-

Decreased function in medial prefrontal cortical areas. Anterior Cingulate BA 25, BA 32 in veterans with PTSD compared to veterans without PTSD during viewing of combat-related slides and sounds. Z score > 3.00 ; $p < .001$

Figure 16.5 Effects of combat-related slides and sounds on brain function. Identified area shows decreased blood flow with combat slides and sounds in combat veterans with PTSD. This area normally inhibits the amygdala (involved in fear responses).

wick, McGlashan, Staib, et al., 2003). A similar failure of activation in the anterior cingulate/medial prefrontal cortex was seen in women with abuse and PTSD while performing an emotional Stroop involving naming the color of a word like "rape" (Bremner et al., 2004). These findings were similar to prior imaging studies in PTSD from our group using trauma-specific stimuli for symptom provocation, adding further supportive evidence for a dysfunctional network of brain areas involved in memory, including the hippocampus, medial prefrontal cortex, and cingulate, in PTSD.

Other studies have used MRI to look at structural changes in other brain areas besides the hippocampus in childhood abuse. One study used single voxel proton magnetic resonance spectroscopy (proton MRS) to measure relative concentration of N-acetylaspartate and creatinine (a marker of neuronal viability) in the anterior cingulate of 11 children with maltreatment-related PTSD and 11 controls. The authors found a reduction in the ratio of N-acetylaspartate to creatinine in PTSD relative to controls (DeBellis, Keshavan, Spencer, & Hall, 2000). Studies have also found smaller brain size and smaller size of the corpus callosum in children with abuse and PTSD relative to controls (DeBellis, Keshavan, et al., 1999). In a study of abused children in whom diagnosis was not specified, there was an increase in T2 relaxation time in the cerebellar vermis, suggesting dysfunction in this brain region (Anderson, Teicher, Polcari, & Renshaw, 2002).

We developed a method for assessing neural correlates of fear conditioning in abuse-related PTSD. In the fear conditioning paradigm, pairing of a light with a shock leads to a fear reaction to the light alone, an effect mediated by the amygdala. Women with early childhood sexual abuse-related PTSD ($n = 8$) and women without abuse or PTSD ($n = 11$) underwent measurement of psychophysiological responding as well as PET measurement of cerebral blood flow during habituation, acquisition, and extinction of conditioned fear conditions. During habituation, subjects were exposed to a blue square on a screen, 4 seconds in duration, eight times at regular intervals over 90 seconds. During acquisition, exposure to the blue square was paired with an electric shock to the forearm. With extinction, subjects were again exposed to the blue square but without shock. On the 2nd day, subjects went through the same procedure but with random electric shocks (an equal number as on day 1) during the acquisition phase. The control paradigm was identical to the acquisition of conditioned fear paradigm, with the exception that subjects underwent scanning during sensitization trials instead of acquisition of conditioned fear trials for scans 3 and 4. Subjects underwent

sensitization trials, which involved exposure to the conditioned stimulus (blue square) and random electric shocks not paired with the conditioned stimulus. Both PTSD patients and control subjects showed activation of the amygdala with acquisition of conditioned fear (pairing of unconditioned stimulus and conditioned stimulus) relative to the control condition ($p < .005$). Greater left amygdala activation during fear conditioning was seen in PTSD patients relative to comparison subjects (Figure 16.4). Extinction of fear responses was associated with decreased function in the orbitofrontal and medial prefrontal cortex (including the subcallosal gyrus, BA 25, and anterior cingulate BA 32) in the PTSD patients, but not in the controls (Bremner et al., in press). Extinction of fear responding was associated with a greater decrease in medial prefrontal function (anterior cingulate, BA 25, 32, 24) in PTSD compared to controls. These findings are consistent with increased amygdala function in PTSD.

TRAUMA AND PHYSICAL HEALTH

The multiple levels of analysis approach also requires an examination of the relationship between traumatic stress and physical disorders, which may act directly or through trauma-related disorders like depression and PTSD. Traumatic stress has a wide range of effects on behavior and health (Proctor, Harley, Wolfe, Heeren, & White, 2001; Proctor et al., 1998; Wagner, Wolfe, Rotnitsky, Proctor, & Erickson, 2000; Zatzick et al., 1997). Work from the Centers for Disease Control showed that early adverse events are associated with dramatic increases in anxiety, substance abuse, obesity, and variables such as smoking that represent a risk factor for heart disease (Dube, Felitti, Dong, Giles, & Anda, 2003; Williamson, Thompson, Anda, Dietz, & Felitti, 2002). The cardiovascular system is particularly sensitive to stress and emotion (Berkman, Vaccarino, & Seeman, 1993; Krumholz et al., 1998; Rozanski, Blumenthal, & Kaplan, 1999). Increased risk of heart disease was associated with depression (Anda, Williamson, & Jones, 1993), anxiety, and personality (Mendes de Leon et al., 1998; Musselman, Evans, & Nemeroff, 1998; Rozanski et al., 1999). Laboratory studies showed an increase in ischemia with mental stressors like mental arithmetic in certain vulnerable individuals (Arrighi et al., 2000; Arrighi, Burg, Cohen, & Soufer, 2003; Burg, Jain, Soufer, Kerns, & Zaret, 1993; Soufer et al., 1998). Mental stress was also associated with a decrease in heart rate variability (Lampert, Ickovics, Viscoli, Horwitz, & Lee, 1998), which increases the risk of sudden death

from arrhythmia. Patients with acute stressors were found to have a reversible left ventricular dysfunction with myocardial inflammation on biopsy; markedly elevated levels of plasma epinephrine and norepinephrine showed that the patients were under severe stress (Wittstein et al., 2005). One study found an increased risk of cerebrovascular disease in veterans who had undergone captivity stress during WWII; the risk was compounded by a diagnosis of PTSD (Brass & Page, 1996). Other studies have shown a relationship between stress, PTSD, and heart disease (Boscarino, 1997; Engel, Liu, McCarthy, Miller, & Ursano, 2000).

Epidemiological studies have established a relationship between episodes of Major Depression, which is often linked to stress, and cardiovascular events in patients with (Barefoot, Helms, & Mark, 1996; Carney, Rich, & Freedland, 1988; Frasure-Smith, Lesperance, Juneau, Talajic, & Bourassa, 1999; Frasure-Smith, Lesperance, & Talajic, 1993) and without (Anda et al., 1993; Barefoot & Schroll, 1996; Ford et al., 1998; Fredman, Magaziner, Hebel, Hawkes, & Zimmerman, 1999; Hippisley-Cox, Fielding, & Pringle, 1998; Pratt et al., 1996) a prior history of coronary heart disease (CHD). Episodes of depressed mood were associated with a triggering of myocardial ischemia (Gullette, Blumenthal, & Babyak, 1997). Depression is associated with an increased risk of mortality, which is primarily related to increased cardiovascular death, particularly in men (Wulsin, Vaillant, & Wells, 1999).

The mechanisms through which depression increases CHD risk are unclear. Depression could increase CHD risk through its known association with unhealthy behaviors, such as lack of exercise, smoking, and poor diet, or through direct effects on the cardiovascular system (Hemingway & Marmot, 1999; Musselman et al., 1998; Wulsin et al., 1999). Stressful life events have been linked to the onset of episodes of Major Depression (Kendler et al., 2000), but it is not known whether stress leads to both heart disease and depression independently, or whether stress mediates an effect on heart disease through the development of depression.

Elevations in cortisol and sympathetic function in depressed individuals could lead to cardiac events through several possible pathways. Increased sympathetic function leads to increases in heart rate and blood pressure, which is associated with endothelial injury, platelet aggregation, and increased vascular reactivity (Musselman et al., 1998). These factors are all associated with increased risk of myocardial infarction. Some studies have directly linked changes in platelet aggregation and vascular reactivity with depression (Musselman et al., 1998). Stress (which in-

creases the risk of depressive episodes) results in increased cortisol and norepinephrine release, as well as increased heart rate and blood pressure (Bremner, Krystal, et al., 1996a, 1996b), which can impact negatively on cardiovascular function. Studies in monkeys using social stress (in which dominance hierarchies are changed over time) have demonstrated a relationship between stress and accelerated cardiovascular disease (Kaplan, Manuck, Clarkson, Lusso, & Taub, 1982). Monkeys undergoing stressors had increased activation of the cortisol and norepinephrine systems, which was associated with acceleration of the development of atherosclerosis. Stressed monkeys also developed increased endothelial injury, which led to increased platelet aggregation and plaque formation at the site of the injury. These effects were shown to be blocked with propranolol, the beta-adrenergic receptor antagonist, indicating that the effects were mediated through norepinephrine (Kaplan, Manuck, Adams, Weingand, & Clarkson, 1987). Stress also resulted in impairment in endothelial responsiveness to acetylcholine. Elevated morning plasma cortisol levels have been related to coronary atherosclerosis in young and middle-aged men (Troxler, Sprague, Albanese, Fuchs, & Thompson, 1977). An excess in cortisol level may increase the risk for cardiovascular disease by injuring the intima (Kemper, Baggenstoss, & Slocumb, 1957; Nahas, Brunson, King, & Cavert, 1958) or by inducing inflammation in the artery wall (Gabay & Kushner, 1999; Musselman et al., 1998).

The effects of traumatic stress on heart disease might be mediated through brain areas sensitive to stress that are affected by PTSD, including the amygdala, medial prefrontal cortex, hippocampus, posterior cingulate, and anterior cingulate. These brain circuits have direct or indirect outputs through the hypothalamus and medial prefrontal cortex to neurohormonal systems (cortisol, norepinephrine) that influence myocardial function. For instance, the hippocampus and medial prefrontal cortex (which includes the anterior cingulate) have inhibitory pathways to the amygdala (Milad & Quirk, 2002; Morgan & LeDoux, 1995; Morgan, Romanski, & LeDoux, 1993; Phillips & LeDoux, 1992), which plays a critical role in the stress response (Davis, 1992; Hitchcock & Davis, 1986; Hitchcock, Sananes, & Davis, 1989; J. L. LeDoux, 1993; Miserendino, Sananes, Melia, & Davis, 1990; Rosen & Davis, 1988). In addition to activating increased arousal and fear behaviors, the amygdala has pathways through the lateral hypothalamus that activate cortisol and sympathetic pathways in the periphery (Hitchcock & Davis, 1991). Other brain areas implicated in a study of CHD patients (who were hostile

but without psychiatric disorder) who experienced mental stress-induced ischemia included the parietal, temporal, and visual cortex and dorsolateral prefrontal cortex. Also, activations and deactivations were seen in different parts of the prefrontal cortex, including the medial prefrontal cortex and anterior cingulate. Some of these regions were involved in the cognitive and visual appraisal of the stress or in the mathematics (visual, parietal, temporal cortex; Soufer et al., 1998). The medial prefrontal cortex and anterior cingulate are unique in also mediating directly cortisol and sympathetic responses through direct connections to the brain stem (Diorio et al., 1993). The amygdala has a direct pathway to the lateral nucleus of the hypothalamus that stimulates the peripheral stress response system. The hippocampus has direct inputs to the amygdala. The posterior cingulate also has connections with these regions and is involved in visuospatial processing of threat. These brain regions are included in the list of limbic regions (J. E. LeDoux, 1996). Cats with a loss of the cerebral cortex have increased sympathetic responses (MacLean, 1949; Papez, 1937); this neurohormonal activation is critical for survival. However, with chronic stress and chronic activation, these neurohormonal systems lead to changes in the endothelium, acceleration of atherosclerosis, alterations in heart rate variability, increased risk for arrhythmias, increased platelet aggregation, and other factors that increase the risk for cardiovascular mortality after stress. In our ongoing studies, we are finding that patients with a history of traumatic stress and depression have increased stress-induced myocardial ischemia measured with cardiac single photon emission computed tomography. These patients experienced ischemia in the absence of chest pain. Our ongoing twin study shows very high rates of undetected heart disease in depression, measured with cardiac PET. It could be that exposure to traumatic stress with the negative outcome of depression is necessary for the development of stress-induced ischemia. There could be a large number of patients with depression and traumatic stress who are at risk for heart disease. The increased mortality after heart attack could be due to stress-induced episodes of ischemia that put vulnerable myocardium at risk.

MULTIPLE LEVELS OF ANALYSIS

Traditionally, researchers have approached problems from a single dimension. For instance, epidemiologists focus on prevalence of disease and risk factors in the population at large. Psychologists and psychiatrists focus on groups of

patients, often funneled to the same clinic because they have similar complaints. Or there may be a group of investigators in an engineering department who have a nifty technology that could provide vital clues about a group of patients with a mental disorder, but they don't want to be bothered with driving across town to meet with a group of behavioral researchers or mental health clinicians. You may have a situation where two different groups, say, psychosocial epidemiologists and behavioral psychologists, are studying essentially the same phenomena but conversing in a different jargon, publishing in different journals that the other group never reads, attending different meetings, sending grants to different study sections, and basically knowing nothing of the parallel culture. You can point to a similar disjunct between biological psychiatrists and developmental psychologists. Cardiologists treat heart disorders caused by sadness or stress and have no idea what the true etiology is of their patients' disorders.

The language of the new National Institutes of Health "road map" is aimed at batting down such barriers between research groups and disciplines. It talks about the need to eliminate "silos" and promote interdisciplinary research. Although we all can agree that more cross-fertilization will help everyone, the fact is that sometimes people in silos are actually battened down in bunkers, fighting a war to keep the money flowing in so that they can continue an independent line of research.

However, because researchers have always gone and will continue to go where the money is, it seems that the new road map ushers in a new way to look at the old problems. And what way is that? It seems to mean getting out of the straitjacket of looking at a single dimension of a problem such as traumatic stress and looking at the problem from multiple levels at the same time (Cicchetti & Dawson, 2002). This means thinking about the impact of trauma from the standpoint of biology, psychology, individual meaning, spirituality, and other dimensions. Most psychological research is based on self-report data provided by subjects about the symptoms they are experiencing. However, they may have arrived at this point from multiple pathways; therefore, self-report data may not be helpful, and in fact may even be misleading. Adding biological or genetic data to the self-report data may better inform the phenotype, leading to a view of the endophenotype (Kagan, Snidman, McManis, Woodward, & Hardway, 2002).

Biological mediators may also have an impact on psychological outcomes (Kopnisky, Cowan, & Hyman, 2002). For instance, in the aftermath of traumatic stress, there can be preoccupation and rumination that lead to memory

rehearsing. This memory rehearsing can lead to feelings of upset, with enhanced cortisol and norepinephrine outflow, which modulate memory and actually change how memory is stored. Activation of the amygdala and decreased function in the prefrontal cortex further enforce the circuitry that maintains the memory. However, teaching individuals how to let these thoughts go and to prevent endless cycles of rumination about the trauma through meditation and self-healing may prevent the consolidation of the memory circuits that maintain indelible memories and reduce long-term anxiety (Bishop et al., 2004; Bishop & Sativhari, in press).

There are other ways a multiple-levels-of-analysis approach can better inform our models of mental illness. One can look specifically at the domain of clinical neuroscience and see that a multilayered approach is necessary, even discounting other disciplines. Specifically, the initial assumption was that the advent of brain imaging (and genetics) would help us find “the lesion” that was responsible for the disorder. However, years of research have shown that this is not the case, forcing us to fall back on models of circuits of multiple regions functioning (or dysfunctioning) in tandem to lead to symptoms of the disorder (Johnson, Halit, Grice, & Karmiloff-Smith, 2002).

Looking at the issue of development represents another face of the multidimensional cube. Psychiatric disorders in adults have a fairly uniform and continuous face, at least on the surface. However, to follow psychopathology in children, throughout the developmental periods of infancy, childhood, adolescence, and finally into adulthood, can be like following Alice through the looking glass. Symptoms that appear as one disorder in one stage of development can look very different in another stage of development (Harrington, Rutter, & Fombonne, 1996). Adding the element of trauma makes things even more confusing. We know very little about how risk and resilience influence children’s responses to trauma. Children seem to flip from one diagnosis to another throughout childhood, and there is little consensus about what is going on here (Harrington et al., 1996; Saigh et al., 2000). On top of that, assessment of PTSD in children has been notoriously difficult (Saigh et al., 2000).

Because a variety of mediators and modulators can influence the eventual outcomes of the trauma response, a multilevel analysis would be beneficial. Individuals could be born with an inherent resilient constitution that makes them resistant to the effects of the trauma (Bonanno, 2004). An inherently strong social support network (Keane et al., 1987) or lack of previous traumas (Bremner, South-

wick, Johnson, Yehuda, & Charney, 1993) may positively affect long-term outcome. Our understanding of these variables is limited by the fact that most research on trauma was conducted with Vietnam veterans 20 years after their trauma exposure. Before 1990, the diagnosis of PTSD was never made by VA clinicians (Bremner, Southwick, Darnell, & Charney, 1996), even though the diagnosis was established in 1980. To understand why some individuals develop chronic PTSD from early abuse and others don’t, we can’t wait until 20 years after the fact. Research is needed longitudinally to follow traumatized individuals through the different stages of development to assess the effects of trauma using multiple layers of analysis.

CONCLUSIONS AND FUTURE DIRECTIONS

Trauma has effects on multiple levels, including psychological, biological, physical, social, and political. At times, biological correlates of traumatic stress can become metaphors for individual, political, and social responses to trauma. Understanding all of these facets is important because they often cannot be separated. For instance, a person’s sense of meaning may be altered after trauma, but that may be driven by the physiological changes associated with the trauma. And recovery may involve a spiritual process that in fact changes brain function. The public health implications of biological changes with childhood abuse are also relevant. If childhood stress and maltreatment leads to an inhibition of neuronal growth and/or damage in brain areas such as the hippocampus that are critical for new learning and memory, this could have detrimental effects on the ability of children to succeed in school. Also, if stress results in dysfunction of brain areas such as the medial portion of the prefrontal cortex that are involved in the regulation of social behavior, early stress could lead to a biological vulnerability to future acts of antisocial behavior, leading to a vicious cycle of repeated violence and abuse.

Looking at traumatized patients from a multiple-levels-of-analysis approach has implications for treatment and future directions of research. By throwing out the one disease/one etiology model, the limitations of a single treatment are highlighted. In the future, we need to go beyond thinking of a single medication or psychotherapy treatment being applicable to all traumatized patients. Medications like the SSRIs do have a role to play, but other aspects of the traumatized patient need to be addressed as well. Tools that can be given to patients to help themselves can be very powerful. For instance, meditation has been shown to in-

crease overall sense of control (Weissbecker et al., 2002) through a positive accepting mode of control (Astin, 1997). Meditation may provide a way for trauma victims who are vulnerable to PTSD to experience a greater sense of control in relation to their thoughts and memories and to be less emotionally reactive to their presence in the midst of other activities. For example, if a distressing memory/thought is noticed, no attempt is necessarily made to change it. Thus, the focused attention required to sustain the thought (with its attendant distress) is diverted, preventing the escalation of negative thoughts into ruminative patterns (Teasdale, Segal, & Williams, 1995), which in turn can lead to increases in negative psychological states such as mental distress and depression (Teasdale et al., 2000). This process may also prevent the rehearsing and replay of traumatic memories that may modify the way they are stored and make them indelible or resistant to further modification. Reduction of negative thoughts and behaviors may also promote self-healing through the promotion of positive rather than negative behaviors and coping styles.

More attention needs to be paid to the ability of trauma victims to heal themselves in other ways. Our focus on the disease model in PTSD carries the assumption that trauma is always a bad thing that inevitably leads to psychopathology. However, many individuals are extremely resilient in the face of trauma and report their reaction in the aftermath of trauma as a growth experience (Bonanno, 2004). Some patients are better left alone, or can help themselves through programs of self-healing.

Future research needs to examine the role of such alternative approaches in helping trauma victims in their recovery. Studies also need to go beyond the false dichotomies of mind/brain/body and address the important effects that stress has on physical health, perhaps mediated through the brain. Then treatments of physical disorders can incorporate elements of behavior, emotion, spirituality, and cognition that are closer to the root of the distress. Studies also need to incorporate in their designs multiple outcomes of behavior, spirituality, physical indicators, brain measures, cognitive assessments, and the multitude of factors that go into the development of distress. These studies should be performed longitudinally, so that the interaction between physical, neural, emotional, and psychological development and trauma can be fully assessed. More attention is needed to research that goes beyond the boundaries of discipline or expertise, including studies on the relationship between stress and physical disorders like heart disease, and the play between genetics and mental symptoms. In promoting a multiple-levels-of-analysis approach, we may be getting

closer to what is really bothering our patients and have a better chance at giving them the best treatments.

Exponential growth in knowledge of the interactions among the central and peripheral nervous systems and the immune system has been achieved in the past 3 decades (Ader, 1981, 2000; Ader, Felten, & Cohen, 1991; Ader, Cohen, & Felten, 1995). The signals and routes via which psychological and physical stressors lead to endocrine and immune responses have been studied extensively. Theorists, applied researchers, and professionals are extrapolating these basic findings to consider how individual differences in psychological states might be associated with immunity, illness susceptibility, and negative health outcomes (see Cohen & Herbert, 1996; Herbert & Cohen, 1993b; Kemeny & Gruenewald, 1999; Kemeny & Laudenslager, 1999; Kiecolt-Glaser & Glaser, 1995). By contrast, how such processes affect children's immunity has received only scant empirical attention (e.g., Adamson-Macedo, 2000; Boyce et al., 1995; C. K. Coe, 1999; C. L.

Coe, 1996). Although developmental science should be concerned with the ultimate impact of these phenomena on children's health and well-being, and additional research with this particular emphasis seems to be a high priority, the focus of this chapter is on another leading edge of psychoneuroimmunologic research (e.g., Maier & Watkins, 1998a, 1998b; Maier, Watkins, & Fleshner, 1994) that has substantially altered assumptions regarding the direction and nature of effects among the brain, behavior, and immunity (e.g., Blalock, 1994; Dantzer, 2001).

Our overarching objective is to introduce a new world of ideas to developmental scientists and to reveal how the implications of this new knowledge extends into their realm of inquiry and influences theories about the origins of individual differences in and extremes of behavior (Cicchetti & Lynch, 1995; Gottlieb, 1992). To place these ideas into a meaningful context, a historical overview of our

understanding regarding the neuroendocrine immune (NEI) network is provided. Whenever possible, road maps to seminal papers for interested readers are offered. We assume that developmental psychopathology has only rarely cross-trained its students in immunology, and therefore we digress to introduce the basic features of the immune system with an emphasis on its proposed function as our “sixth sense.” Then the concomitants and consequences of the intracellular regulatory molecules of the NEI network (e.g., cytokines) for the brain and ultimately behavior are described with direct reference to their association with developmental psychopathology. Next, we review the available evidence that supports immune system-stimulated changes in central nervous and endocrine systems during early development as they effect permanent changes in these processes as well as in social behavior that persists into adulthood. Genetic-developmental and social environmental forces are also explored as examples of potential moderators of the developmental effects of early illness on later life outcomes. Collectively, the findings support the biological plausibility that the search for environmental forces that shape microevolution and individual development has largely overlooked a large class of ubiquitous and omnipresent stimuli: physical antigens such as viruses, bacteria, and toxins. We conclude by presenting a theoretical model of how psychoneuroimmunologic processes affect developmental plasticity, and we make recommendations for research to integrate such ideas into developmental science in the next generation of studies.

THE NEUROENDOCRINE IMMUNE NETWORK: ABBREVIATED HISTORY OF THE SCIENCE

Robert Ader (1996, 2000) has thoughtfully documented the history of science linking behavior and psychological states to changes in immune function. He describes a modern set of assumptions that has evolved from a series of major discoveries that punctuate three major eras of inquiry. The first era spans the turn of the prior century through the early 1950s. During this period, the field of immunology made substantial strides and expanded our understanding of lymphoid cell and tissue function, antibody specificity and activity, and most other basic features of the immune system. These advances had profound implications for research and treatment of infectious disease, allergy, cancer, and tissue rejection/transplantation. But classically trained immunologists of this time were in some respects myopic. It was determined that the central nervous system (CNS) lacked a lymphatic system to drain its tissues and capture

potential antigens and was protected from infiltration of many soluble substances (i.e., cytokines) and the inward migration of lymphoid cells by the blood-brain barrier (Benveniste, 1992a, 1992b). Correspondingly, the dominant assumption was that the CNS operated relatively isolated from, and independent of, the immune system. The CNS was considered an immunologically privileged site. There was no available evidence to support the biological plausibility that the immune system might be influenced by psychological, cognitive, affective, or behavioral states. With only a few exceptions, this set of ideas attracted little or no empirical attention. There were some Russian scientists (Kopeloff, Kopeloff, & Raney, 1933) who published findings in the 1930s suggesting that components of the immune response could be classically conditioned (see Ader, 1996), but this potentially groundbreaking work was largely overlooked by the scientific establishment. Needless to say, the possibility that the immune system may affect the brain and behavior was never addressed in the scientific literature of this time.

Observations made by George Solomon (1969; Solomon, Amkraut, & Kasper, 1974; Solomon & Moos, 1965), then working at Stanford University, are considered by many to have initiated a paradigm shift in the 1960s. Solomon and his colleagues reported clinical evidence of associative relationships between socioemotional events and immune activity. He claimed that individual differences in symptoms of autoimmune arthritis varied as a function of social and psychological features (conflict, cohesion, emotional climate) of the family environment (Solomon & Moos, 1965). Unfortunately, as with the observations of the Russian scientists 30 years earlier, Solomon’s reports were not well received by the scientific establishment. They did attract attention, but they were largely dismissed as being “biologically implausible.” Journal editors and study sections serially rejected his manuscripts and proposals, and in the face of strong resistance to his ideas, he temporarily closed his laboratory due to lack of support.

The evidence of “biological plausibility” that Solomon needed to support the veridicality of his clinical observations was not obtained until the late 1970s and early 1980s. Anatomical pathways were discovered that physiochemically linked the central nervous and lymphoid systems (see Figure 17.1). Most notably, a team led by David and Susan Felten at the University of Rochester identified specific efferent nerve tracts that terminated in lymphoid tissues and organs, including the spleen (D. L. Felten, Ackerman, Wiegand, & Felten, 1987), lymph nodes (D. L. Felten et al., 1984), thymus (Williams et al., 1981), and appendix (D. L. Felten, Overhage, Felten, & Schmedtje, 1981). Receptors

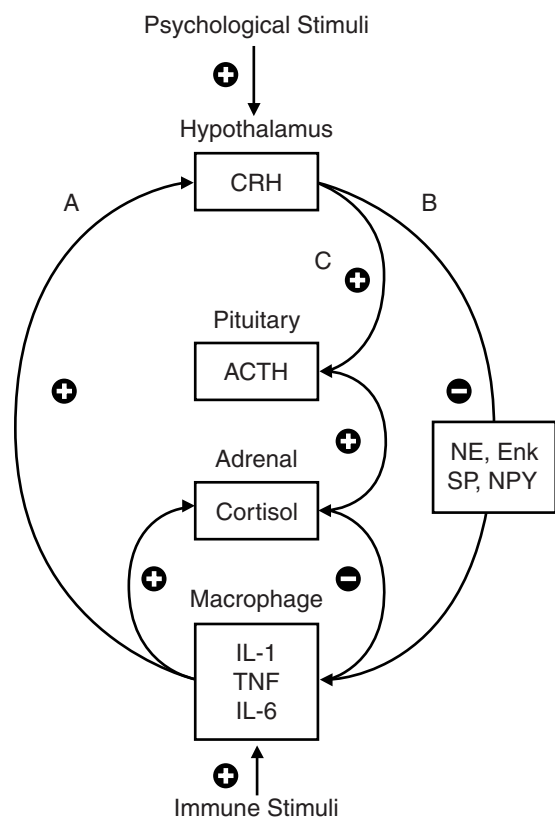

Figure 17.1 Schematic representation of the neuroendocrine-immune system and its signaling routes and molecules. Pathway A indicates the immune-to-brain communication link via the activity of cytokines (IL-1 = Interleukin-1; IL-6 = Interleukin-6; TNF = Tumor necrosis factor). Pathway B indicates the communication route between the autonomic nervous system (ANS) and the immune system (ENK = Enkephalin; NE = Norepinephrine; NPY = Neuropeptide YSP = Substance P). Pathway C indicates the communication link between the Hypothalamic-pituitary-adrenal axis and the immune system (ACTH = Adrenocorticotropic hormone; CORT = Cortisol or corticosterone; CRF = Corticotropin-releasing hormone). Plus (+) and minus (−) identify pathways with primarily excitatory or inhibitory effects. *Source:* From “Developmental Psychoneuroimmunology: The Role of Cytokine Network Activation in the Epigenesis of Developmental Psychopathology” (pp. 293–323), by D. A. Granger, N. A. Dreschel, and E. A. Shirtcliff, in *Neurodevelopmental Mechanisms in Psychopathology* by D. Cicchetti and E. Walker (Eds.), 2003, New York: Cambridge University Press.

were identified on lymphoid cells for a variety of the products (e.g., epinephrine, norepinephrine) secreted by these nerve terminals (S. Y. Felten, Felten, Bellinger, & Olschowka, 1992). Lymphoid cell function was altered in the presence of these substances. Then it was established that the hypothalamic-pituitary-adrenal (HPA) axis (i.e., adrenocorticotropic hormone, glucocorticoids) and autonomic nervous systems (i.e., substance P, neuropeptide Y,

norepinephrine) were able to communicate with lymphoid cells via releasing factors and hormones secreted into the general circulation (see Carr, Radulescu, DeCosta, Rice, & Blalock, 1992). These discoveries of both hard-wired and soluble chemical messenger routes of communication served to establish the scientific legitimacy of studying interrelationships among the brain, behavior, and immunity (Ader, 1981; Ader et al., 1991; Kiecolt-Glaser & Glaser, 1989). Subsequently, research focused on explaining individual differences in links between stress, behavior, and health risk as mediated or moderated by the effects of psychological states on immune function. Research reports from this effort now fill many of the pages of health-oriented scientific journals, such as *Health Psychology*, *Annals of Behavioral Medicine*, *Brain, Behavior and Immunity*, and *Psychosomatic Medicine*.

The interested reader is referred to a meta-analytic review on stress and immunity by Herbert and Cohen (1993b). Briefly, the review reveals that subjective experiences related to stress are capable of suppressing immune activity. However, there are several important caveats. The effects are not necessarily consistent within any or across the many different compartments of the immune system (see later discussion). The magnitude of the suppressive effect, averaging across all available studies, is approximately 10%. The duration of effects is best characterized as a temporary “delay” rather than an absolute shutdown in any particular immune process.

Although the basic immunosuppressive effect of stress on immunity is consistently observed across studies, there remain questions regarding the clinical significance and ultimate impact on health of such effects. That is, only a handful of studies (e.g., Cohen, Tyrell, & Smith, 1991) have come close to *causally* linking stress-induced suppression of immune activity in humans to increased risk for negative health outcomes. The small magnitude and short duration of these effects, when considered in light of the complexity of the immune system (adaptability, broad range of normative activity, extensive redundancy between subsystems), suggest that a causal link is unlikely. Indeed, it takes a substantial stretch of the imagination to consider why a causal link would have adaptive significance. This realization has influenced the drift in National Institutes of Health funding priorities away from basic research questions on the links between stress and immunity.

During the late 1960s and 1970s, basic research on the immune system progressed at a very rapid pace. One discovery was paramount. Until this time, it was assumed that cellular communication within the immune system depended largely on physical cell-to-cell contact. This set of

assumptions was challenged by Gale Granger and colleagues (e.g., G. A. Granger & Williams, 1968; Hessinger, Daynes, & Granger, 1973) at the University of California, Irvine. In a series of landmark studies, they revealed that cells of the immune system secreted soluble chemical messengers of their own to initiate, maintain, and regulate cellular immune responses. These messengers were originally defined as “lymphokines,” and for years their effects were considered to be limited to the immune system. More important, for present purposes, it was discovered that these lymphokines (see Maier & Watkins, 1998b; E. Smith, 1992; Vilcek, 1998) also had “hormonal” effects on non-lymphoid cells at considerable distances from the cells that secreted them. Receptors for these molecules were also identified on cells of the central nervous and endocrine systems (e.g., Besedovsky et al., 1983; Besedovsky & Del Rey, 1989). In recognition of their functional diversity, this group of molecules was relabeled cytokines in the early 1980s. Since that time an explosion of information has accumulated about these molecules and their effects. For instance, a computerized search of Medline using cytokine as the keyword yields more than 299,255 publications on the topic.

For the budding field of psychoneuroimmunology, this wave of new information completed a critically important communication loop. It was biologically plausible that the immune system could both receive *and* send biochemical signals to the central nervous system (see Figure 17.1). These advances stimulated a shift in our assumptions regarding how the brain, behavior, and immune system influenced one another (see Maier & Watkins, 1998a, 1998b). Today, a third era of understanding and research on psychoneuroimmunology has evolved that has been heavily influenced by technical and theoretical advances made during the 1990s (declared by the U.S. Congress as “the decade of the brain”). Psychoneuroimmunology research has attracted considerable attention from molecular biologists and neuroscientists (Ader, 2000; Altman, 1997). The findings from their efforts are unequivocal: Cells of the lymphoid, central nervous, and endocrine systems use the same hormones, neurotransmitters, and other critical effector molecules to send and receive signals among one another. These once considered independent systems are now viewed as sharing a common set of signaling molecules and receptors and “speak” a similar chemical language (Ader et al., 1991; Blalock, 1994, 1997; Maier & Watkins, 1998a).

Our contemporary assumptions are that the brain, endocrine system, and immune system constitute an interactive information network, with each node capable of affecting and being affected by the activity of the others

(Ader, 2000; Black, 1995; Cotman, Brinton, Glaburda, McEwen, & Schneider, 1987). A schematic diagram of these interactive systems with representative signaling molecules and communication routes is depicted in Figure 17.1. Pathway A indicates the immune-to-brain communication link triggered by immune activation and carried forward via the activity of cytokines, such as interleukin-1 (IL-1) tumor necrosis factor (TNF) and interleukin-6 (IL-6). Consequences involve activation of the HPA axis at the level of the hypothalamus, pituitary, and adrenal. Pathway B indicates the communication route between the autonomic nervous system (ANS) and the immune system involving signals such as norepinephrine (NE), enkephalin (ENK), substance P (SP), and neuropeptide Y (NPY). Pathway C indicates the communication link between the HPA axis and the immune system (CRF = corticotropin-releasing hormone; ACTH = adrenocorticotrophic hormone; CORT = cortisol or corticosterone). Consequences of the activation of pathways B and C involve suppression of the immune response. The interconnection of these pathways (A to BC and back to A) is considered highly adaptive. This negative feedback loop from the ANS and HPA axis prevents the inflammatory response from proceeding unchecked and damaging the host.

OVERVIEW OF THE IMMUNE SYSTEM

A basic understanding of the immune system is fundamental to thinking about its potential interactions with behavior and developmental psychopathology. Here we provide an introductory (101-level) overview to highlight its key properties and functional divisions. Some of the key immune component processes are described in sufficient detail so the naïve reader can appreciate the immune system’s complexity. Interested readers are referred to introductory texts by Janeway (2005) and Goldsby (2003) for additional basic background information and are also encouraged to audit a basic immunology course.

Basic Properties and Divisions

The immune system functions to protect individuals from infectious organisms, microbes, transformed cells (virally infected or malignant), and toxins. To do this, it has the capacity to (1) distinguish between cells and molecules that belong (self antigens) and those that do not belong (nonself antigens); (2) destroy foreign antigens without doing damage to the host; and (3) record antigenic experience so the immune response is more efficient and effective later, if re-exposure occurs (Clough & Roth, 1998). The immune sys-

tem is divided into two functional branches: innate or natural immunity and specific or acquired immunity.

Innate or Natural Immunity

These mechanisms are termed natural because they do not require exposure to a foreign agent to be acquired. They are present at birth or develop over the course of maturation without environmental input. This is the first line of defense against invading microorganisms. Natural immunity is composed of physical, mechanical, and chemical barriers found on all body surfaces. For example, skin is acidic and its surface is composed of a cornified, nonviable, impervious layer of cells. Internal body surfaces (mucus membranes) are washed by a continuous flow of mucus, which can contain antibacterial enzymes and peptides, termed defensins. If a surface barrier is breached, the invading organism is immediately confronted by various types of lymphoid cells (e.g., macrophages, neutrophils). Mobilized from the blood stream or found in the local tissue, phagocytic cells (e.g., macrophage) ingest and digest nonself antigens. If the organism gains entrance into the blood stream, it will be confronted by large numbers of phagocytic cells located in the spleen and liver. These cells also include a specialized subpopulation of lymphocytes, termed natural killer (NK) cells. NK cells identify and destroy cells that are virally infected or transformed (malignant). The majority of nonself antigens and invading organisms are stopped from infecting the host by the innate immune system's first line of defense.

Specific or Acquired Immunity

As opposed to natural or innate defenses, the adaptive immune response only becomes operative when the nonspecific natural barriers are breached. At this point, the host is infected. Organisms and materials that activate the immune response are called antigens (Ags) and must be foreign to the host immune system. The immune system distinguishes foreign from self by differences in the shape of the Ag when compared to self molecules. The most effective Ags are usually large, complex molecules; for example, proteins and carbohydrates are the best, whereas lipids and nucleic acids, though large, are not complex and therefore are least effective. But small molecules can become immunogenic if they can covalently link to a larger carrier molecule. When this occurs, the complex is termed a hapten.

Cells and Tissues

The lymphoid system comprises interconnected vessels and organs disseminated throughout the body but missing in the

central nervous system. Lymphatics are an interconnected system of vessels and associated lymph nodes located in most body tissues. Lymphatic vessels have multiple functions: (1) facilitate lymphoid cell movement, (2) return fluids from tissues back to the blood stream, and (3) collect foreign materials that have entered our tissues. Lymph nodes capture and localize foreign materials in the lymph fluid and are primary sites of the specific immune response. Gut-associated lymphoid tissue collects and responds against materials that gain entrance into tissues via the gastrointestinal tract. The spleen and bone marrow are lymphoid tissues that capture foreign materials that gain entrance into the blood stream. Bone marrow is the source of stem cells, which can reconstitute the lymphoid system.

During development in utero, one population of lymphocytes leaves the bone marrow and enters the thymus, where they acquire the capacity of self-recognition and migrate into the lymphoid tissue; they are termed T lymphocytes. A second population of lymphocytes leaves the bone marrow and migrates directly into the lymphoid tissues; these are termed B lymphocytes. Mononuclear phagocytes are derived from the bone marrow. T and B lymphocytes and monocytes can be found circulating in blood and lymph, but the majority are localized in lymphatic tissues. As will be shown in a subsequent section, lymphocytes collaborate to recognize, destroy, and eliminate foreign Ags.

Ontogeny

The immune system in humans becomes functional 2 to 4 months after birth but does not completely mature until puberty (see Figure 17.2). The newborn human is protected during the first few months after birth by maternal antibodies (Ab)/immunoglobulins (Ig). Antibodies are proteins

Figure 17.2 Curvilinear trajectory of immune system ontogeny.

secreted from lymphocytes (B cells) and will be fully explained in a subsequent section. Maternal antibodies are passed to the fetus via the placenta and passed to the newborn via colostrum during early breast-feeding. Maternal Ab gradually decay, and the immune system of the newborn gradually becomes functional. There are also cases of genetic and acquired complete or partial immunodeficiency in both adults and children. The functional capacity of the immune system declines as we reach old age. The rate and timing of this decline vary from individual to individual but generally starts during the 6th decade of life and continues until death. This decline is not due to a loss of lymphoid cells but to their ability to respond to new Ags.

Primary and Secondary Response

The immune response generated to the first exposure of an individual to an Ag is termed the *primary response*. The timing and level of response depend on the route of entry, how distinct the Ag is from self, and the amount of Ag involved. There are two components to the immune response: formation of soluble proteins by B lymphocytes (Abs) and cell-mediated immunity (CMI) residing in populations of T lymphocytes. One or both types of response may occur to a single Ag. Antibodies appear within 3 to 5 days in the serum of an individual during the primary response. The levels continue to rise for 15 to 20 days, and then, as they induce destruction of the Ag, level off and decline to a low baseline level, which is maintained for long periods. If the Ag is an infectious agent, the host may show clinical symptoms and recover if the agent can be destroyed. Upon reexposure to the same Ag, Abs appear in a few hours and the levels rise much higher than those reached in the primary response. The host may not show signs of infection, and Ab levels can remain high for long periods. This *secondary response* phenomenon is the scientific basis for the concept of booster shots. Subsequent exposure to Ag (such as booster shots) keeps the levels of protective Ab high for long periods (see Figure 17.3).

Steps Involved in Initiation

Initiation of the immune response involves multiple steps and cell types. The first step is the ingestion of the Ag by mononuclear phagocytes located in the area where natural barriers have been breached. These phagocytes, termed Ag presenting cells, digest the Ag into small pieces, then express the pieces in combination with special receptors on the exterior of the plasma membrane. The Ag presenting cells then migrate into a lymphoid tissue, and the membrane complex is presented to helper CD4+ T lymphocytes. The helper cells then activate small populations of Ag-

Figure 17.3 Specificity, memory, and regulation of immune response. Antigens A and B induce the production of different antibodies (specificity). The secondary response to antigen A is more rapid and larger than the primary response (memory). Antibody levels (titers) decline with time after each immunization (regulation).

specific T and/or B lymphocytes. Once activated, the Ag-specific T and B cells rapidly expand their numbers. The effector T lymphocytes are responsible for cell-mediated immunity and the B lymphocytes differentiate into Ab-forming plasma cells. Cytokines secreted by activated cells at each step are the stimulus that promotes both cellular differentiation and proliferation. The end result of this process is the generation of large numbers of Ag-specific T cells and specific Abs whose job it is to leave the lymphoid tissues and inactivate and destroy the Ag. The humoral Ab response is referred to as TH1 type reaction, and cellular immunity is referred to a TH2 type response. After the destruction and removal of the Ag, memory T and B cells can remain in lymphoid tissues for years. These long-lived memory cells can rapidly respond upon a second contact with the specific Ag.

Antibodies/Immunoglobulins

There are five classes of antibodies/immunoglobulins in humans that are an interrelated family of proteins. The most predominant classes are IgG, IgM, IgA, IgD, and IgE. IgM is the first Ab formed, followed by IgG, which becomes the major class in serum. IgA is found in serum and is also the major class in body secretions. Only a minor-class IgE is often the culprit responsible for most allergies. All classes of Ab can be formed with the same specificity against a single Ag. Each class can have a different functional capability. Each class of Abs is formed by assembly of distinct heavy (2) and light (2) peptide chains folded together to form a Y-shaped molecule. Each complete molecule has two identical

Ag binding sites at the ends of the Y. Serum IgG, IgE, IgD, and IgA are single units, and IgM and secreted IgA are polymers of 5 and 2 monomer units, respectively. Various portions of the molecule are referred to as either “fragment with Ab activity” (FaB) or “fragment crystallizable” (Fc), based on digestion of the molecule with proteases.

Cell-Mediated Immunity

The mediators of cellular immunity are antigen specific T lymphocytes. They possess a specific Ag-recognizing receptor expressed on their external plasma membrane. The T cell receptor is able to recognize Ag only when it has been processed and is complexed to special receptors expressed on the external membrane on most body cells. These Ag-reactive T cells are referred to as cytotoxic T cells (CTL) and cytokine-releasing cells.

Adaptive Immunity: Effector Phase

Once initiated, the purpose of the immune response is to inactivate and destroy the foreign antigen(s). There are two broad classes of immunity: *humoral*, mediated by immunoglobulins, and *cellular*, mediated by immune T cells.

Effects of IgM, IgG, and IgA

Abs molecules have multiple specific binding sites for the Ag. Once bound to an Ag, they can cause neutralization of enzymes, toxins, and viral particles. They also localize the Ag by forming Ag-Ab complexes with both soluble and particulate Ags. These Ag-Ab complexes can activate secondary mechanisms, which help in the destruction of the Ag. The complement system is a family of 9 proteins, found in both serum and tissue fluids, which are activated in a cascade fashion to result in formation of the “attack complex” and in release of several chemo-attractant peptides. The attack complex causes cell lyses and the peptides induce immigration of phagocytic cells from the blood stream. Phagocytes can recognize Ag-Ab-complement complexes and will phagocytose and digest the entire complex. The NK cell can also recognize an Ab-coated cell and cause its destruction. The NK cell must make physical contact with the Ab-coated cell. This class of cytotoxic reactions is termed antibody-dependent cellular cytotoxicity (ADCC).

IgE Allergies

IgE is the main but not the only cause of most allergic reactions. Allergies occur in families and affect a large percentage of the human population. The IgE molecule has the unique ability to bind via the tail or Fc portion of the mole-

cule to mediator-containing basophils and mast cells. These mediator-containing cells are widely distributed in body tissues and in the blood stream. An individual can become allergic by exposure to Ag, formation of IgE, and coating of mast and basophil cells with IgE. Subsequent exposure to Ag results in specific release of histamine, chemokines, and lipid mediators, which induce the tissue changes associated with allergies. The severity of these reactions is affected by a variety of factors, including IgE levels, mast cell reactivity, and amount of Ag reaching the mast cells.

Cell-Mediated Immunity

Cell-mediated immunity is those classes of reactions mediated by immune cytotoxic and cytokine-releasing T lymphocytes. Cytotoxic T lymphocytes (CTL) recognize processed Ag peptides complexed with receptors on a target cell surface. They identify these peptides via a specific T cell receptor on the surface of the CTL. Subsequent interaction of membrane proteins on both cells induces the CTL to destroy the target cell via two mechanisms: deposition of cytolytic enzymes on the target cell surface, which induces membrane disruption, and secretion of chemokines and cytokines, which can induce inflammation and a slower form of cell death (apoptosis). This type of immunity is important in destruction of allografts, virus-infected cells, tumor cells, and self cells in various forms of autoimmune disease.

Although CTL and cytokines secreting T cells do not have a direct effect on microorganisms, they are important in microbial immunity. They exert their effects by recruiting and activating blood monocytes to become highly phagocytic macrophages, which can ingest and destroy the microorganism. The T cells are stimulated to release chemokines and cytokines by interaction with processed microbial Ags on the surface of tissue-fixed mononuclear phagocytes at the site of infection. These mediators induce emigration of monocytes from the blood stream into the affected tissue, and they are further induced to differentiate into macrophages. The activated macrophage has the ability to destroy the microorganism via its increased phagocytic and digestive capacity. This type of reactivity is very important in resistance to different types of bacterial, fungal, and viral infections. These reactions also have a role in tumor immunity and various types of autoimmune syndromes and have been termed delayed hypersensitivity (DTH).

Summary

Natural resistance mechanisms serve to slow the initial progress of a pathogen while the adaptive immune system

becomes engaged. Once initiated, soluble antibodies, secreted by plasma cells in lymphoid tissue, reach the site of infection via the blood stream and neutralize and localize the pathogen and soluble toxins and enzymes. The Ag-Ab complex is formed and the complement system is activated, which can kill certain pathogens and will induce emigration of phagocytes from the blood stream into the site of infection. Phagocytes recognize the Ag-Ab complement complexes and ingest and digest them. Later, Ag-specific T cells enter the site, become activated to secrete cytokines, induce monocytes from the blood to enter the tissue, and activate to become macrophages. The activated macrophages also ingest and destroy the Ag-Ab complexes. Once the Ag is removed, the normal healing process can begin and the tissue is repaired and returned to normal.

THE IMMUNE SYSTEM AS OUR “SIXTH SENSE”

Decoding the syntax of the NEI axis has enabled theorists to attribute new features to the immune system's already extensive functional repertoire. Blalock (e.g., 1994, 1997) was among the first to propose that the immune system recognizes unique environmental stimuli (i.e., viruses, bacteria, microbes, toxins) that are essentially undetectable by our classic visual, auditory, olfactory, and gustatory sensory systems. More specifically, one cannot see, hear, smell, taste, or feel an individual microbe. However, the immune system is designed to recognize and respond to 10^9 different specific antigens. Just as is true with our other sensory inputs, when the immune system recognizes such stimuli, the encounter is converted into a cascade of biochemical messages. We now know that those messages are responsible for inducing changes in the host's metabolic, thermogenic, and behavioral states in response to infection.

The adaptive significance of the biobehavioral (metabolic, thermogenic) reaction to systemic infection provides a supportive physiologic environment for the immune system to fight pathogens most effectively. For example, increased sleepiness combined with reduced activity, motivation, and arousal may conserve energy stores needed by the immune system. It might seem paradoxical to have a decreased appetite when sick (one is sacrificing calorie and protein intake by not eating), but it is adaptive for a sick animal in the wild not to forage for food, but to stay in one place, conserving energy and avoiding predators (Hart, 1988). Fever is stimulated by action of proinflammatory molecules (cytokines and acute phase proteins) on the hypothalamus. These signals produce an unfavorable environ-

ment for the growth of many microbial pathogens (see Kluger, 1979). For instance, the rate of bacterial growth is consistently slower in environments with temperatures greater than 98°F. The afflicted individual's expression of sickness behaviors (see subsequent discussion) also serves an adaptive purpose. The sick are more socially inhibited and withdrawn, a behavior change that conveys benefits to the individual, as noted, but also to the population and immediate social group. In the cases of communicable infectious pathogens, social withdrawal of those infected limits the exposure of others to the agent of disease.

The advances in our understanding of the interactions among the immune, central nervous, and endocrine systems reveal that individual differences in biobehavioral responses to infection may be relevant to developmental science in ways previously unrealized. Characterizing the immune system as a sixth sense highlights the biological plausibility that immune system-to-brain communications represent a largely unexplored pathway through which individual differences in experience with environmental factors (nonself antigens) shape and reshape the structure and function of biological systems underlying behavior. With few exceptions (e.g., Adamson-Macedo, 2000; C. L. Coe, 1996; Crnic, 1991; Shanks, Larocque, & Meaney, 1995), this set of ideas has attracted only minimal attention from mainstream psychoneuroimmunology or developmentally oriented researchers. Figure 17.4 presents a summary of the major shifts in the evolution of our knowledge regarding the central nervous system and the immune system, as well as the corresponding assumptions regarding the links between the immune system and behavior.

A PRIMER ON CYTOKINES FOR DEVELOPMENTAL SCIENTISTS

In this section, we describe the general properties of cytokine (the critical effector molecules thought to mediate the aforementioned sensory functions) and how peripherally activated cytokines communicate with and affect the brain, endocrine system, and behavior. Readers interested in additional detail are referred to Maier and Watkins (1998b), who present an overview of cytokines for psychologists, or S. W. Granger and Ware (2003). *The Cytokine Handbook*, fourth edition (Thomson & Lotze, 2003), provides basic detail on individual cytokines as well as their interactions and therapeutic uses. As this is a rapidly expanding area of knowledge, interested readers may also find cutting-edge information in scientific journals such as *Science*, *Nature*, *Cell*, *Journal of Experimental Medicine*,

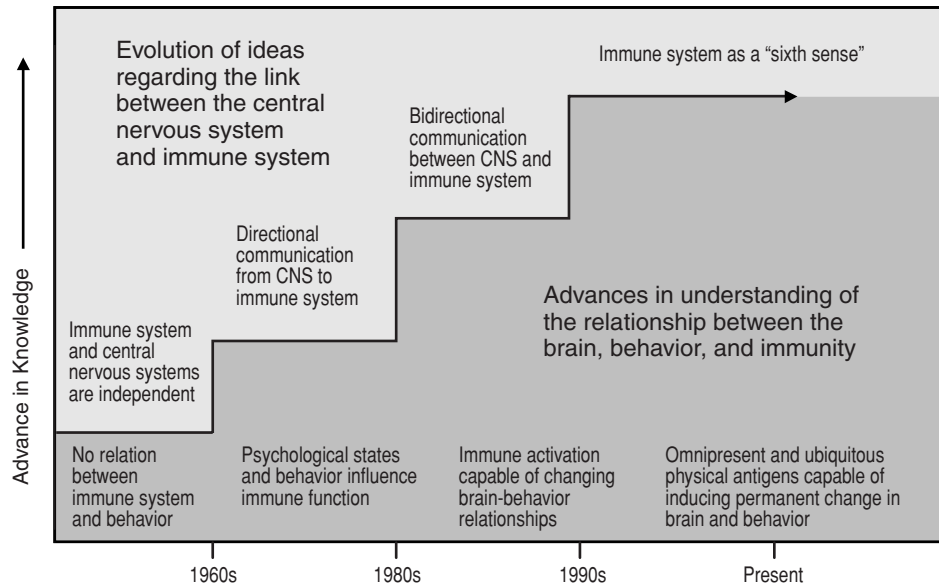

Figure 17.4 Advances in our understanding of the link between the central nervous system and the immune system has progressed in a stepwise function over the past 50 years. The basic developments have profoundly changed our assumptions about how the immune system effects and is influenced by behavioral and psychological states.

Basic Properties and Functions

Although work on lymphokines and interferons (two types of molecules now recognized to have cytokine actions) began in the 1960s, it wasn't until 1974 that the term cytokine was proposed to describe the entire class of molecules with these properties (Vilcek, 1998). Since then, the number of molecules that have cytokine-like properties has been expanding at a very rapid pace. This can be attributed to technological advances in molecular biology and genome sequencing, which have led to the discovery of more than 200 members. In fact, a relatively new family of molecules called chemokines has experienced its own wave of discovery, leading to the identification of four subfamilies of these molecules, totaling 47 members in all. Hence, the complexity of this network continues to grow as the intertwining biologic functions of these molecules are elucidated.

Cytokines are small protein molecules that act as intercellular messengers (see Goldsby, 2003; Thomson & Lotze, 2003). They range in size from 8 to 30 kiloDaltons

(kDa) and induce their effects as soluble or membrane-bound proteins by binding to high-affinity receptors on target cell membranes. Unlike hormones, cytokines usually act over short distances in an autocrine or paracrine fashion. Virtually all nucleated cells can produce cytokines, but white blood cells are the major source. Monocytes and macrophages are especially efficient cytokine producers. Some cytokines are stored preformed in the intracellular granules for instantaneous release. However, most cytokine secretion involves de novo protein synthesis, a process that takes hours.

Cytokines are pleiotropic, meaning they have multiple target cells and multiple actions, and their effects are often redundant, sometimes synergistic; they often induce the production of other cytokines and are less frequently antagonistic. They play important roles in maintaining health and are the causative agents in disease. In addition to regulating immune and inflammatory responses, the biologic consequences of cytokine signaling are critical for development, growth, healing, and maintenance of just about every tissue and organ of the body. Cytokines can be grouped into families according to their structure, common receptor usage, and whether they have predominantly anti-inflammatory, proinflammatory, chemotactic, or growth-promoting functions. Within the immune system, in general, interleukins (e.g., IL-1 through IL-28) are molecules that have a functional activity involving leukocytes; colony-stimulating and growth factors (e.g., IL-3,

G-CSF, m-CSF, GM-CSF) promote cell proliferation of hematopoietic and somatic cells; tumor necrosis factors (e.g., TNF, lymphotoxin, FasL, TRAIL, BAFF, CD40L, OX40L) initiate inflammation, orchestrate the development and maintenance of lymphoid organs, and regulate

lymphocyte homeostasis and proliferation; interferons (e.g., INF- α / β and INF- γ) act to interfere with viral replication; and chemokines (e.g., CC and CXC chemokines) are chemotactic agents that recruit leukocytes to sites of inflammation and orchestrate lymphoid architec-

TABLE 17.1 Representative Members of the Cytokine Family and Some of Their Major Biological Activities

Family	Representative Members	Secreted By	Major Biological Activity
Interleukins (IL1–IL29)	Interleukin-1 (IL-1 α , IL-1 β)	Monocytes/macrophages	Induces synthesis of acute-phase proteins Induces fever Stimulates lymphocyte activation
	Interleukin-2 (IL-2)	T Lymphocytes	Induces T lymphocyte proliferation Enhances activity of NK cells
	Interleukin-4 (IL-4)	T Lymphocytes	Stimulates T and B lymphocyte proliferation, Th2 polarization Increases phagocytic (ingestive) activity of macrophage
	Interleukin-6 (IL-6)	Monocytes/macrophages	Induces synthesis of acute-phase proteins Stimulates antibody production
	Interleukin-10 (IL-10)	T Lymphocytes	Suppresses macrophage cytokine secretion Down-regulates antigen presentation
	Interleukin-12 (IL-12)		Stimulates cellular immune responses, Th1 polarization
Interferons	Interferon gamma (IFN- γ)	NK cells/T lymphocytes	Enhances activity of macrophages Induces proliferation of B lymphocytes Inhibits viral replication
	Type I Interferon (IFN) IFN α and IFN β	IFN α - Neutrophils, dendritic cells IFN β - fibroblasts	MHC class I induction, antiviral, anti-proliferative
Colony-stimulating and growth factors	Transforming Growth Factor β (TGF- β)	Macrophages/lymphocytes	Induces macrophage IL-1 production Limits inflammatory response and promotes wound healing
	Granulocyte Macrophage Colony Stimulating Factor (GM-CSF)	T lymphocytes/activated macrophages	Stimulate the formation of macrophages, neutrophils, eosinophiles, and basophiles
	Granulocyte Colony Stimulating Factor (G-CSF) Macrophage Colony Stimulating Factor (M-CSF)		
Tumor necrosis factor superfamily (TNFSF1–TNFSF18)	Tumor Necrosis Factor (TNF)	Macrophages	Has cytotoxic (cell-killing) effects Induces cytokine secretion Associated with chronic inflammation
	Lymphotoxin (LT/TNF β)	Lymphocytes	Development and maintenance of lymphoid organs, chemokine induction
	CD40L	Lymphocytes	T cell proliferation
	FasL	Lymphocytes	Apoptosis, lymphocyte homeostasis
	BAFF	Myeloid cells	B cell survival
	TRAIL	Most normal tissues	Apoptosis
	OX40, CD27L, 4-1BBL	Antigen-presenting cells	T cell costimulation
Chemokines CC chemokines (CCL1–CCL28), CXC chemokines (CXCL1–CXCL16), C chemokines, and CX3CL1	IP-10 (CXCL10)	Monocytes	Chemotaxis, adhesion, histamine release
	IL-8 (CXCL8)	Epithelial cells	Neutrophil recruitment
	Rantes (CCL5)	T cells	Chemoattraction of leukocytes

ture and leukocyte trafficking. The nomenclature hints at their major functions, but most cytokines have extremely diverse effects (Clough & Roth, 1998). Some specific examples of cytokines and their main biological functions in the immune system are listed in Table 17.1.

Cytokine Regulation

Cytokines are extremely potent signaling molecules, and their presence even in very low pg/ml (picogram per milliliter) levels can induce substantial cellular consequences. A complex set of mechanisms exists to prevent cytokines from doing damage to the host. At least three types of endogenous cytokine inhibitors have been identified: cytokine antagonists (e.g., IL-1ra), molecules homologous to cytokines and able to bind cytokine receptors without leading to signal transduction; shed cytokine receptors (e.g., s-TNF-R type I and II), which bind cytokines in the intercellular fluid space and stop it from reaching its target cell or tissue (Gatanaga, Hwang, et al., 1990; Gatanaga, Lentz, et al., 1990); and other molecules that act through independent receptors that exert opposite effects on the cell (Thomson & Lotze, 2003). Some cytokines also inhibit each other (e.g., IL-10 inhibits synthesis of TNF, IL-1, IL-6, and others).

The regulation of cytokines is complex and has profound consequences for the host. Inadequate production of cytokines will result in an insufficient cellular immune response and a potentially negative outcome related to pathogenesis of the microbe or virus (see Figure 17.5). Without medical intervention, individuals expressing consistent hypoarousal of the cytokine network would be unlikely to survive. It is highly likely that in nature, this phenotype would be removed from the gene pool within one generation, as these individuals would succumb to pathogenesis (or predation). On the other hand, excessive cytokine secretion has been linked to “sickness behaviors” (see subsequent discussion), autoimmune disorders (i.e., arthritis), neurological disease (e.g., multiple sclerosis), toxic shock, and death (i.e., sepsis; see Figure 17.5). It is plausible that in populations under selective pressure, individuals expressing hyperarousal of the cytokine network would also be removed from the gene pool. That is, when challenged by immune stimuli, these individuals would experience severe fatigue, fever, loss of appetite, inactivity, social withdrawal, weight loss, and cognitive slowing, which together significantly increase risk of predation. Thus, in the wild, selective pressure from microorganisms and predators may serve to regulate the gene pool such that reproductively fit individuals have cytokine networks that operate within an optimal range of function (see Figure 17.5).

Figure 17.5 Individual differences in the activity of the cytokine network have an inverse parabolic relationship with physical and mental health. Regulation of cytokine activity within an optimal range is essential to avoid the negative biobehavioral consequences linked with either hypoarousal or hyperarousal of the immune system. *Source:* From “Developmental Psychoneuroimmunology: The Role of Cytokine Network Activation in the Epigenesis of Developmental Psychopathology” (pp. 293–323), by D. How Peripherally Activated Cytokines Talk to the Brain

The most well-characterized pathway through which peripheral immunological stimuli signal changes in the brain begins with the macrophage. When activated, macrophages secrete a cascade of cytokines and other chemical messengers (see Table 17.1). Of particular importance, it is the cytokine products released in response to immune stimulation, not the direct effect of the immunological stimulus (e.g., bacterial or viral pathogenesis), that are thought to mediate many of the resulting changes in the brain (Dantzer, Bluthé, & Goodall, 1993; Dinarello, 1984a, 1984b).

Molecular, cellular, and in vivo evidence suggests that macrophage-derived interleukin-1 (IL-1) has the most systemic and hormonal-type effects of all the cytokines (E. Smith, 1992), with widespread consequences for the brain (Weiss, Quan, & Sundar, 1994). Two forms of IL-1 exist, α and β (Dinarello, 1988, 1992). IL-1 β is the dominant soluble, biologically active form in the circulation and brain (Benveniste, 1992b; Chensue, Shmyre-Forsch, Otterness, & Kunkel, 1989; E. Smith, 1992). Peripheral administration of nanogram amounts of IL-1 β stimulate corticotropin-releasing factor (CRF) from hypothalamic neurons (Harbuz & Lightman, 1992; Sapolsky, Rivier, Yamamoto, Plotsky, & Vale, 1987; Woloski, Smith, Meyer,

Fuller, & Blalock, 1985), resulting in increased circulating levels of ACTH and corticosterone (Dunn, 1988, 1990). Interestingly, reports by Berkenbosch (Berkenbosch, de Goeij, Del Rey, & Besedovsky, 1989; Berkenbosch, De Rijk, Del Rey, & Besedovsky, 1990; Berkenbosch, Van Dam, De Rijk, & Schotanus, 1992) and Dunn (e.g., Chuluyan, Saphier, Rohn, & Dunn, 1992; Dunn, 1992a, 1992b) demonstrate that peripheral administration of IL-1 β may also potentiate the HPA axis response to environmental challenge. IL-6 and TNF are functioning similar to IL-1 β in that they also stimulate the HPA axis during inflammatory stress (E. Smith, 1992).

Cytokines have a variety of effects on cerebral neurotransmission (see Dunn & Wang, 1995; Dunn, Wang, & Ando, 1999). IL-1 β acts to stimulate cerebral norepinephrine (NE) metabolism, probably reflecting increased synaptic release. IL-1, IL-6, and TNF also stimulate indoleamine metabolism of tryptophan and decrease the concentration of serotonin (5-HT). Through their action on indolamines, cytokines also affect the synthesis of quinolinic (QUIN) and kynurenic acid (see Figure 17.6). QUIN is an agonist of the N-methyl-d-aspartate (NMDA) receptor and other excitatory amino acid receptors. These receptors mediate excitatory amino acid neurotransmission in the hippocampus, basal ganglia, and cerebral cortex and, when activated for sufficient periods, have been implicated

in nerve cell death and dysfunction (Heyes, 1992; Heyes, Brew, et al., 1992; Heyes, Quearry, & Markey, 1989; Heyes, Saito, et al., 1992; Saito, Markey, & Heyes, 1992). On the other hand, kynurenic acid is an antagonist of NMDA receptors and could modulate the neurotoxic effects of QUIN as well as disrupt excitatory amino acid transmission. Heyes and colleagues report that QUIN and kynurenic acid are mediators of neuronal dysfunction and nerve cell death in inflammatory diseases. A schematic diagram of the cerebral effects of cytokines is depicted in Figure 17.6.

It is apparent that many of the peripherally stimulated effects on the central nervous system result from activation of IL-1 β in the brain (Quan, Sundar, & Weiss, 1994). That is, within hours after peripheral immune activation, expression of IL-1 β transcripts is induced in the hippocampus, hypothalamus, and pituitary (Ban, Haour, & Lenstra, 1992; Laye, Parnet, Goujon, & Dantzer, 1994). Studies also show that IL-1 receptors are widely distributed throughout the brain and endocrine tissues (Cunningham & De Souza, 1993), with high densities observed in the hippocampal area and the choroid plexus (Takao, Tracy, Mitchell, & De Souza, 1990). Thus, it is not surprising that the behavioral and physiological effects can be mimicked by administration of IL-1 β directly into the brain (Weiss et al., 1994) and that they can be attenuated by intracerebraventricular in-

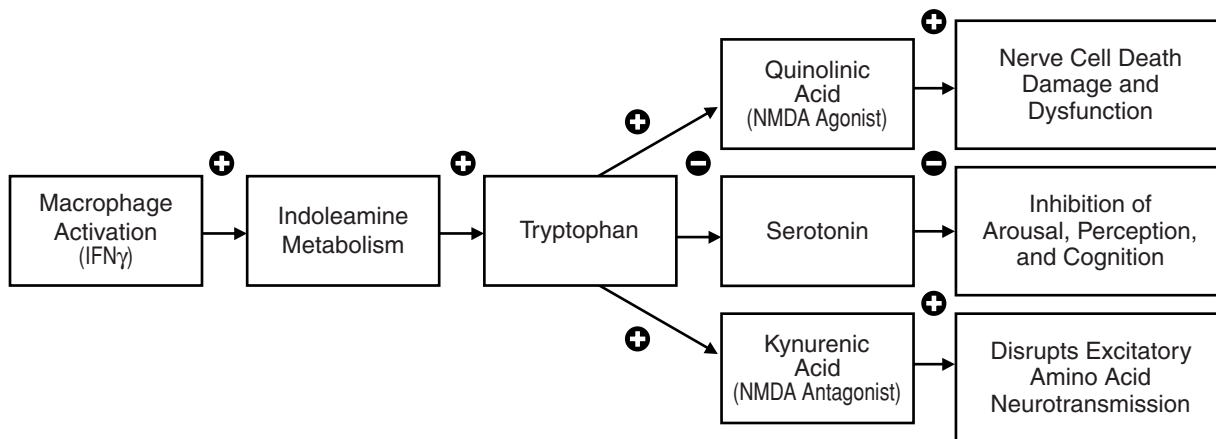

Figure 17.6 Immune activation has a variety of effects on cerebral neurotransmission. Bacterial, viral, fungal, and parasitic infections result in macrophage release of cytokines, including those that activate indoleamine-2,3-dioxygenase (IDO). Increases in IDO activity accelerate the degradation of L-tryptophan to neuroreactive kynurenines, including the excitotoxin quinolinic acid (QUIN) and the antagonist of excitatory amino acid receptors, kynurenic acid (KYNA). QUIN and KYNA influence the activity of N-methyl-D-aspartate (NMDA) receptors. Degradation of L-tryptophan via this kynurenic pathway results in reduced serotonin levels. Consequences of this immune-to-brain pathway include neural damage and dysfunction, neurologic deficits and neurodegeneration, and inhibition of arousal, perception, and cognition. *Source:* From “Developmental Psychoneuroimmunology: The Role of Cytokine Network Activation in the Epigenesis of Developmental Psychopathology” (pp. 293–323), by D. A. Granger, N. A. Dreschel, and E. A. Shirtcliff, in *Neurodevelopmental Mechanisms in Psychopathology*, by D. Cicchetti and E. Walker (Eds.), 2003, New York: Cambridge University Press.

jection of the IL-1 receptor antagonist, IL-1ra (Bluthe, Dantzer, & Kelley, 1992).

Interestingly, IL-1 β in the general circulation does not cross the blood-brain barrier in humans. Rather, peripheral release of IL-1 β somehow signals cytokine synthesis within the CNS. Studies suggest that this process proceeds by both humoral and neural pathways (see Dantzer, Konsman, Bluthe, & Kelley, 2000). The first studies carried out on the mechanisms by which peripheral immune stimuli signal the brain to induce fever, activation of the HPA axis, and sickness behavior emphasized parts of the blood-brain barrier (the circumventricular organs) that allow proinflammatory cytokines to act on the brain. Rodents have circumventricular organs but humans do not, raising an important question regarding the communication route in humans. In the mid-1990s, it was discovered that the subdiaphragmatic section of the vagus nerve attenuates the brain effects of systemic cytokines, suggesting that the mechanism in humans involves cytokine induction in the brain. Since then, neuroanatomical pathways have been confirmed that reveal a fast route of communication from the immune system to the brain via the vagus nerves. In rodents, this neural afferent pathway complements a humoral pathway that involves cytokines produced locally at the circumventricular organs and in the brain parenchyma (see reviews by Dantzer, Bluthe, Gheusi, et al., 1998; Dantzer, Bluthe, Laye, et al., 1998; Dantzer et al., 2000).

In summary, the biological pathways via which cytokines affect the central nervous system have been well characterized. The effects of cytokines in the brain involve changes in neurotransmission in brain regions (i.e., limbic system, hypothalamus), with well-established links to learning and memory, emotion regulation, and the psychobiology of the stress response.

It is tempting to speculate that humans' sweeping elimination of natural predators and widespread application of medical interventions to eradicate infectious diseases (i.e., antibiotics, immunizations) may have created an opportunity for the expression of a wide range of individual differences in the activity of the cytokine network in the modern human population. The next sections detail our understanding of the links between immune activation and behavior and cytokines and psychopathology.

CYTOKINES AND THE BEHAVIORAL SURFACE

The pioneering work of Robert Dantzer at the Neurobiologie Integrative, INSERM, Bordeaux, has defined the cutting edge of our knowledge regarding the behavioral effects of cytokines. Numerous animal model studies show

that IL-1 β administration elicited anorexia (Hart, 1988; Moldawer, Andersson, Gelin, & Lundholm, 1988), increased sleep time (Opp, Orbal, & Kreuger, 1991), decreased social and nonsocial exploration (Sparado & Dunn, 1990), decreased sexual activity (Avitsur & Yirmiya, 1999), increased defensive withdrawal, and affected other behaviors characteristic of the nonspecific symptoms of sickness (Dantzer, 2001; Dantzer et al., 1993; Dunn, Antoon, & Chapman, 1991; Kent, Rodriguez, Kelley, & Dantzer, 1994; Kreuger, Walter, Dinarello, Wolff, & Chedid, 1984). At the behavioral level, some suggest that "sickness behavior" is the expression of a disruption in motivation and arousal that reorganizes the organism's priorities to cope with infectious pathogens (Aubert, 1999; Dantzer, 2001; Gahtan & Overmier, 2001).

Mild to moderate levels of cognitive and behavioral effects of peripherally released cytokines, such as IL-1 β , can be recognized in any person with an active systemic influenza infection. That these effects are commonplace and are experienced to some degree by all of us is illustrated by the sea of hands raised in unanimity when introduction to health psychology students are asked, "Do you agree that your behavior, appetite, and interest in sleep and sex are different when you are sick?" By contrast, only about one-third of the hands are raised when the complementary question, "How many have had the experience of getting sick soon after experiencing a major life event (e.g., loss of a loved one or pet, breakup with a significant other, major challenge in your job or school)?" is asked. Our common experience is consistent with a robust pattern emerging in the literature. That is, the magnitude and breadth of the effects of immune activation at the behavioral surface is considerably more substantial than the effects of our behavior and subjective experience on our immune function.

Tyrell and colleagues (A. P. Smith et al., 1987; A. P. Smith, Tyrell, Coyle, & Higgins, 1988; R. W. Smith, Tyrell, Coyle, & Willman, 1987) rigorously documented adverse effects of experimentally induced respiratory virus infection and cytokine administration on human psychomotor performance, mood, and memory. But the vast majority of information comes from studies of cytokines as biological response modifiers or immunotherapeutics. The discovery of cytokines was considered a major advance in decoding the communication signals used by lymphoid cells, and high expectations were set for their use in treatment of immune-related disease. Clinical trials proved these assumptions to be correct, but there were behavioral and psychological iatrogenic effects that caused many involved as participants in the early trials to withdraw. Many oncology patients treated with cytokines complained of headache, fever, anorexia, fatigue, and social withdrawal

(Gutterman et al., 1982; Mannering & Deloria, 1986). Studies showed that oncology patients treated with cytokines (in this case, interleukin-2 or interferon-alpha) for only 3 to 5 days had significantly higher depression and anxiety symptoms (Capuron, Bluthé, & Dantzer, 2001; Capuron, Ravaud, & Dantzer, 2000, 2001; Capuron, Ravaud, Gualde, et al., 2001). Repeated prolonged exposure to cytokines resulted in increased irritability, short temper, agitation, and aggressiveness; extreme emotional lability, depression, and fearfulness; and more severe symptoms, such as disorientation, paranoia, and suicidal ideation (e.g., Renault et al., 1987). Although these adverse effects were generally attenuated with the termination of the protocol, some participants remained emotionally vulnerable for weeks after the cessation.

In summary, the experimental studies provide strong support for the conclusion that cytokine production (or administration) is causally linked to the expression of change in psychological, emotional, behavioral, and cognitive function. The severity of the symptoms clearly extends into the clinical range. The symptoms linked to cytokines include primarily those related to internalizing (such as cognitive processes, psychosis, anxiety, fearfulness, depression, thoughts about suicide) disorders. Generally, the effects of cytokines at the behavioral surface are consistent with our knowledge about the effects cytokines have on the central nervous and neuroendocrine systems.

INTERNALIZING PROBLEM BEHAVIOR AND CYTOKINES

There have been very few published studies devoted to a comprehensive evaluation of the relationship between psychiatric disorder and cytokine regulation. Some studies report adult patients with severe depression, anxiety, and symptoms of stress-related psychiatric disorders have associated immune abnormalities (e.g., Kelly, Ganguli, & Rabin, 1987; Kronfol, 1999; Kronfol & Remick, 2000). The findings are not always consistent across studies, but the pattern largely supports the hypothesis of an association between internalizing behavior problems and activation of the cytokine network (Connor & Leonard, 1998; Dantzer, Wollman, Vitkovic, & Yirmiya, 1999).

Depression

The rationale that cytokines play a role in the pathophysiology of Major Depression is based on assumptions that (1) depression is closely associated with stress and is often portrayed as an exaggerated response to stress, (2) depres-

sion is accompanied by atypical HPA axis activity, and (3) the cardinal manifestations of depression include changes in sleep, appetite, sex drive, social withdrawal, and cognitive slowing (Kronfol, 1999). There is evidence that cytokines are associated with, or influence, many of these individual symptoms (see Anderson et al., 1996; Herbert & Cohen, 1993a). For instance, in early studies, Maes (Maes, Bosmans, Meltzer, Scharpe, & Suy, 1993; Maes et al., 1995) reported significant elevations of IL-1 β and IL-6 in the plasma of depressed patients. Owen, Eccleston, Ferrier, and Young (2001) report elevated levels of IL-1 β in Major Depression and postviral depression. Musselman et al. (2001) report that cancer patients with depression had markedly higher plasma concentrations of IL-6 than healthy comparison subjects and cancer patients without depression. Berk, Wade, Kuschke, and O'Neill-Kerr (1997) report that levels of c-reactive protein and IL-6 were significantly raised in a group with Major Depression. Suarez et al. (2003) showed that men with Beck Depression Inventory scores of 10 or above (mild- to moderate-level symptoms) exhibited an overexpression of IL-1 β , TNF-alpha, and IL-8. Capuron et al. (2003) recently showed that tryptophan degradation into kynurenine by the enzyme indoleamine-2,3-dioxygenase during immune activation may contribute to the development of depressive symptoms during interferon α therapy.

But Haack and colleagues (1999) caution that the association between depressive symptoms and cytokines may be in part due to incomplete control of numerous potential confounding influences. In one of the largest studies to date (361 psychiatric patients, 64 health controls), they report that once age, body mass, gender, smoking habits, ongoing or recent infectious diseases, and medications are carefully taken into account, plasma levels of cytokines and cytokine receptors yield little, if any, evidence for immunopathology in Major Depression.

Very few studies have explored relationships between psychiatric symptoms or problem behavior and cytokine levels in youth. Birmaher et al. (1994) studied 20 adolescents with Major Depressive Disorder, 17 nondepressed subjects with Conduct Disorder, and 17 healthy controls. Blood samples were drawn for total white blood cells, lymphocyte subsets, NK cell activity, and lymphocyte proliferation assays. Overall, there were no significant between-group differences, but the project did not measure cytokines. A preliminary study in our lab revealed that serum levels of cytokines were significantly correlated with behavior problems in clinic-referred youth but not in nonreferred age-matched comparisons. In the study (M age = 11.3 years, range 8 to 17), it was observed that indi-

vidual differences in serum levels of IL-1 were positively correlated ($r_s(17) = .59$ and $.55$, $p_s < .05$) with self-reported anxiety/depression on the Youth Self-Report version of the Child Behavior Checklist (Achenbach, 1991a, 1991b) and Children's Depression Inventory (Kovacs, 1983) in a clinic-referred group ($n = 20$) but not in a normally developing comparison ($n = 19$) group (D. A. Granger, Ikeda, & Block, 1997). Most recently, Brambilla, Monteleone, and Maj (2004) studied 11 children and adolescents with Dysthymia (DYS), 11 with recurrent Major Depressive Disorder (MDD), and 11 healthy age-sex matched controls. IL-1 β levels were significantly higher in the MDD group compared to controls and were correlated with anxious and depressive symptomatology in the MDD but not in the DYS patients (Brambilla et al., 2004). No studies to our knowledge have yet followed the relationship between depression and immune activation prospectively in youth. Although few in number, the consistency of the findings suggests that this would be a worthwhile next step.

Anxiety Disorders

Depression is often comorbid with anxiety symptoms and other anxiety-related disorders, but data linking cytokines to anxiety disorders are scant. There is a growing body of evidence suggesting a role for autoimmune mechanisms in some specific cases of Obsessive-Compulsive Disorder (OCD; Garvey, Giedd, & Swedo, 1998; Leonard et al., 1999; Swedo et al., 1998). Maes, Meltzer, and Bosmans (1994b) noted a positive association between IL-6 and the severity of compulsive symptoms. Mittleman et al. (1997) reported atypical cytokine levels in the cerebral spinal fluid of patients with childhood-onset OCD. Studies do not consistently support a link between immune abnormalities and Panic Disorders (PD). Brambilla et al. (1992, 1994) reported plasma IL-1 β was significantly higher in patients with PD than controls, before and after treatment with benzodiazepine. Studies by Rapaport and Stein (1994) and Weizman, Laor, Wiener, Wolmer, and Bessler (1999) failed to find that immune measures differentiated patients with PD from normal controls. Spivak et al. (1997) found circulating levels of IL-1 β were significantly higher in patients with combat-related Posttraumatic Stress Disorder (PTSD), with IL-1 β levels correlating with duration of PTSD and severity of anxiety and depression. To our knowledge, no studies have explored relationships between cytokines and anxiety disorders in youth.

The findings to date suggest that cytokines are capable of causing rapid reorganization in behavioral, affective, and cognitive domains; the intensity of such effects ranges

from mild to extreme, and the duration of the effects can outlast the events that precipitated their release. The breadth, magnitude, and duration of the biobehavioral effects of cytokines underscore the plausibility that their dysregulation might alter the organization of human physiology and behavior in ways that affect microevolution and individual development. In particular, accumulating literature highlights the possibility that variation in the expression of socioemotional, cognitive, and behavioral symptoms associated with depression and/or socially inhibited behaviors may be partially explained by differential sensitivities to the effects of exposure to naturally occurring ubiquitous immune stimuli (e.g., see Dantzer, 2001; Kronfol & Remick, 2000; Watson, Mednick, Huttunen, & Wang, 1999). However, although cytokines are sufficient to cause psychiatric symptoms, it is clear that they are *not both necessary and sufficient*; many internalizing psychiatric symptoms and patterns of disorder clearly occur in the absence of cytokine aberrations.

METHODS TO STUDY BEHAVIORAL EFFECTS OF CYTOKINES

Cytokines and their inhibitors can be measured in most biological fluids in the pg/ml (e.g., serum, plasma, urine, cerebrospinal fluid, and possibly saliva) range. There are several approaches, and each has specific advantages and disadvantages. We describe some of the key challenges here and refer the interested reader to more detailed discussions elsewhere.

Traditional in Vitro Methods

There are several challenges to researchers studying cytokine-behavior relationships. Under normal conditions, unless the immune system has been stimulated, the level of most cytokines is in the very low to undetectable range (Wadhwa & Thorpe, 1998). During periods of systemic immune activation, cytokine levels in serum can rise substantially within hours, but there are wide-ranging individual differences. This creates considerable obstacles to evaluating correlates of individual differences as the range of scores is often restricted to present or absent. Also, the variation in levels for the detectable scores can be considerable and is, in our experience, rarely normally distributed. To reveal the full range of individual differences, investigators are often forced to study cytokine responses or production in reaction to an immune challenge. This is

most often accomplished *in vitro*. Blood is collected and lymphoid cells are isolated in single-cell suspension, cultured in media containing bovine serum products and antibiotics, and challenged with a stimulus. After a specified period, the media (supernatant) and/or cells are collected and assayed.

Assay reagents and materials are now widely commercially available, and assays for these biomarkers are routine in most clinical and biomedical research laboratories. *Immunoreactive* cytokine levels would be subsequently assessed using a detection system designed around a highly specific antibody. These methods include competitive radio or enzyme immunoassays (Chard, 1990; Brambilla et al., 2004). These protocols are efficient, economical, and relatively high through-put. They require basic laboratory skills and equipment. The *functional* activity of cytokines is measured using a different approach, called generally bioassays. Here, supernatant from stimulated cultures is applied to a different set of cells (specialized cell-line), and the amount of cytokine bioactivity is extrapolated from the degree of their response (number that grow or die). These tests provide qualitatively different information than immunoassays. They are complex and time-consuming and require advanced laboratory skill and equipment. In addition, many researchers measure cytokine messenger RNA (mRNA) transcripts extracted from stimulated lymphoid cells. These assays require knowledge of polymerase chain reaction techniques. Kiecolt-Glaser and Glaser (1988), Vedhara, Fox, and Wang (1999), and Wadhwa and Thorpe (1998) present overviews of the measurement of the immune response with specific attention to cytokines.

Experimental in Vivo Methods

The ecological validity of *in vitro* data on cytokine levels, bioactivity, and mRNA has been questioned (Kiecolt-Glaser & Glaser, 1988), based on the fact that the cells have been handled, maintained, and manipulated in ways that would not occur in the body. As an alternative to *in vitro* methods, investigators study individual differences or intraindividual change in cytokine production and behavior in whole organisms during acute or chronic illnesses that have inflammatory components. This approach has its own limitations. Are the behavioral consequences of illness in whole organisms (especially in humans) the consequence of the infectious agent itself or of the immune response to that agent? Our overarching assumption is that some individuals generate more proinflammatory cytokines in response to immune challenge and/or that some individuals'

nervous and/or endocrine system components are more sensitive to the effects of cytokines than others'. Correspondingly, we are not particularly invested in the specifics of any particular pathogen or pathogenic process. Rather, we treat the pathogen as a stimulus and are most interested in the characteristics of individuals that create exaggerated cytokine responses or sensitivities when exposed to any number of immune stimuli.

To resolve these issues, in experimental paradigms it is common to employ a standard nonreplicating immune stimulus (e.g., lipopolysaccharide, LPS) as a proxy for systemic viral or bacterial infection (Tilders et al., 1994). LPS (also referred to as endotoxin) is the immunologically active component of gram-negative bacteria cell walls. LPS is derived from bacteria that are endemic to most mammalian species (*E. coli*, *Salmonella*), and vertebrates have specific LPS receptors on the surface of macrophages. Numerous animal studies show that LPS administration mimics the behavioral, neurochemical, and neuroendocrine response to cytokines (i.e., IL-1 β) very closely (see Dunn, 1996). Use of substances like LPS also enables investigators to standardize exposure (e.g., dose by weight, duration of exposure, and strain of virus) to the immune stimulus, a control that is not easy to implement in more ecologically valid contexts. In one of the few studies conducted with humans, Reichenberg et al. (2001) employed a double-blind crossover design with 20 healthy male volunteers. Participants completed psychological questionnaires and neuropsychological tests 1, 3, and 9 hours after intravenous injection of endotoxin (0.8 ng/kg, *Salmonella*). Reichenberg et al. observed that after endotoxin administration, the subjects showed a transient increase in anxiety and depressed mood, with decreased verbal and nonverbal memory. These changes were associated with increased levels of cytokine secretion (i.e., IL-1 β , TNF- α , IL-6) released in response to endotoxin.

Natural Experiments

Interestingly, substances like endotoxin have been used as adjuvants in vaccine preparations (e.g., whole-cell DTP vaccine). Adjuvants are added to stimulate the immune response sufficiently so that adequate antibody is produced to the particular antigen species included in the vaccine preparation. Investigators studying the effects of stress on immunity in adults have often taken advantage of immunizations as natural experiments (Bonneau, Sheridan, Feng, & Glaser, 1993; Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996). Child immunizations offer a similar opportunity. In the United States, for instance, par-

ents are encouraged to have their children immunized starting at 3 months of age and continuing on a regular basis through the preschool years. Studies of immunizations represent a natural experiment in which to explore individual differences in cytokine-behavior relationships (Morag, Yirmiya, Lerer, & Morag, 1998). Several studies predate the current rationale but do show mild to moderate short-term behavioral effects of childhood immunizations (Cody, Baraff, Cherry, Marcy, & Manclark, 1981). The side effects include fever, irritability, lack of appetite, and increased sleep and parallel the nonspecific symptoms of sickness induced by cytokines.

On a side note, in general, we know very little about the determinants of individual, developmental, or gender differences in the expression of sickness behaviors in children. Research on the efficacy of most childhood vaccines was conducted largely before cytokines were known as regulators of the NEI network. For instance, the whole-cell version of the DPT vaccine contained endotoxin as an adjuvant. The vaccine was causally linked to adverse reactions and behavior disorders (e.g., Blumberg et al., 1993; Borg, 1958; Cody et al., 1981; Long, DeForest, Smith, Lazaro, & Wassilak, 1990). A government-mandated scientific panel called for studies of biobehavioral predictors of individual differences in the severity of adverse responses to vaccines, as well as the specific biological mechanisms responsible for vaccine-induced behavioral effects (Howson, Howe, & Fineberg, 1991). The use of the whole-cell DTP vaccine was discontinued in the late 1990s. Thus far, immunizations have been used to study the effects of stress on immunity and health; we highlight the potential of this natural experiment as a model in which to study sickness behaviors and immune-endocrine relationships across the life span.

Noninvasive Measurement in Saliva

The ability to measure biological variables noninvasively in saliva has created many opportunities for behavioral scientists to test biosocial models of individual differences and intraindividual change in mood, cognition, behavior, and psychopathology (Kirschbaum, Read, & Hellhammer, 1992; Malamud & Tabak, 1993). For instance, the integration of salivary measures of steroid hormones such as cortisol (Schwartz et al., 1998), testosterone (D. A. Granger et al., 2004), and dehydroepiandrosterone (D. A. Granger, Schwartz, Booth, Curran, & Zakaria 1999) has become routine in developmental science. Yet, as the number of studies doing so has increased, special circumstances capable of compromising the value of the information generated have been documented. In a series of studies, we show that

the measurement of salivary biomarkers can be substantially influenced during the process of sample collection (Schwartz, Granger, Susman, Gunnar, & Laird, 1998; Shirtcliff, Granger, Schwartz, & Curran, 2001), are susceptible to interference effects caused by the leakage of blood (plasma) into saliva (Kivlighan, Granger, Schwartz, Nelson, & Curran, 2004), and are sensitive to storage conditions when samples are archived (D. A. Granger et al., 2004). Although we show workable solutions to each of these problems, they are raised here because these issues are relevant to the measurement of immune markers in saliva but have yet to be addressed in the literature.

There are other caveats. The immune system is highly compartmentalized, and immune activity in the oral mucosa may reflect a localized response that is relatively independent of the more general systemic level of activation. Indeed, there is a highly specialized literature on oral biology and disease. Consistent with this explanation, and in contrast to the near-perfect linear serum-saliva associations for some endocrine markers (i.e., cortisol), the serum-saliva correlations for immune markers has been shown to be small to modest (Nishanian, Aziz, Chung, Detels, & Fahey, 1998). In our preliminary studies, we have documented the internal validity (i.e., linearity, spike recovery) of experimental immunoassay protocols for sIgA, c-reactive protein, interleukin-6, and surrogate markers of immune activation such as β -2-microglobulin and neopterin. However, important questions remain unanswered: To what degree, and under which circumstances, do the levels of salivary immune markers reflect systemic immune activation? Do individual differences in these parameters provide information beyond the status of the immune system in the oral mucosa? Studies to establish external validity of these markers are now under way.

DO CYTOKINES AFFECT DEVELOPMENTAL PLASTICITY OF THE BIOLOGICAL BASIS OF BEHAVIOR?

It is clear that cytokines cause short-term behavioral changes, but is it possible that activation of the cytokine network could affect the long-term plasticity of biological systems underlying important behavioral, emotional, or cognitive capacities? Can cytokines change enduring aspects of our temperament or personality? The overwhelming evidence of cytokine effects on cerebral and neuroendocrine systems underscores that this may be biologically plausible. Yet, at first glance, this possibility seems to contradict our everyday experience. When adults

have systemic viral or bacterial infections (e.g., influenza, *E. Coli*), the majority clearly express sickness behaviors, albeit to different degrees. But even those of us who become the most agitated, withdrawn, sleepy, and irritable when we are sick return to our regular selves within days after the obvious signs of infection (fever, swollen glands) subside.

Theoretical Background and Biological Plausibility

Are there developmental periods when humans are more susceptible to longer-term or permanent effects? Several facts suggest that humans may be more susceptible earlier than later in life. Each of the main components of the NEI axis develops rapidly during the 1st year of life. As noted earlier, the immune system starts to function 2 to 4 months after birth and does not reach full maturity until puberty. The HPA axis is functional and stress-responsive at birth, but not yet synchronized with a diurnal rhythm. The threshold or set point of cortisol reactivity is substantially influenced by environmental input (i.e., the caregiving environment) during early childhood. The adrenal gland, however, doesn't fully mature until middle childhood—a period of development termed adrenarche that begins for most around age 6 to 8. By contrast, in the last decades of life, the lymphoid system's ability to recognize and respond to antigens declines dramatically, as do levels of most endocrine system products.

Shanks et al. (1995) suggest the possibility that experience with the antigenic environment early is critical with respect to setting the tone of neuroendocrine reactivity throughout life. This logic closely parallels Michael Meaney's (Liu et al., 1997; Meaney, Aitken, Bhatnagar, Van Berkel, & Sapolsky, 1988) behavioral studies showing that characteristics of the early caregiving environment are determinants of individual differences in HPA reactivity in later life. Shanks speculates that the antigenic environment mammals are born into remains remarkably stable throughout life. Thus, she considers the influence of early illness on the developing HPA axis to be adaptive. HPA responsiveness to the secretion of proinflammatory cytokines is essential to regulating the magnitude and duration of the systemic immune response. It follows, then, that the NEI system would not be one size fits all but would have the potential to assimilate and accommodate the antigenic topography early in development. This logic is consistent with the notion that the immune system plays a highly specialized sensory role in this process of fine-tuning the threshold of reactivity for the developing NEI.

To adequately investigate this possibility, studies are needed that employ longitudinal designs and focus on the link between the activity of cytokines (and processes that influence their regulation) and the onset, changes, and continuities of atypical behavioral and biological function. To our knowledge, such studies have yet to be conducted with humans. The evidence from animal studies, however, is revealing.

Effects of Early Illness on Physiology Later in Life

Studies with rodents show conclusively that exposure to immune system products (i.e., cytokines) during early development permanently changes biological systems with well-known organizational influences on the brain and behavior. O'Grady and colleagues (O'Grady & Hall, 1990, 1991; O'Grady, Hall, & Goldstein, 1987) reported that immune activation during pre- and neonatal periods affects changes in the size of the adrenal glands, ovaries, and testes that persist into adulthood. Shanks et al. (1995) showed that immune activation during a critical neonatal period of HPA axis development had profound effects on neuroendocrine (i.e., ACTH, corticosterone) responsiveness to environmental challenge during adulthood. Specifically, administration of endotoxin (0.05 mg/kg) on days 3 and 5 of life resulted in decreased glucocorticoid negative-feedback inhibition of ACTH synthesis, thereby potentiating HPA responsiveness to restraint stress. These studies are perhaps the first to reveal that exposure to immune products early in life can permanently alter neural systems, that is, HPA and hypothalamic-pituitary-gonadal axes, governing the impact of maturational processes and environmental events on development. They suggest indirect effects on behavioral, emotional, and social processes via permanent changes induced in these biological systems.

Effects of Early Illness on Later Behavior

This developmental phenomenon was first extended into the behavioral domain by Crnic and colleagues (Crnic, 1991; Segall & Crnic, 1990). Their studies reveal striking evidence that immune activation in neonates induced behavioral changes that persisted into adulthood. Neonatal mice administered herpes simplex virus or interferon became spontaneously hyperactive for life (Crnic & Pizer, 1988). Of particular importance, this radical reorganization of behavior was mediated by the impact of products of cellular immune activation, not necessarily viral pathogenesis, on the migration of granule cells from the cerebellum.

Crnic's findings are groundbreaking in that they provide solid evidence of neuroanatomical changes induced by immune activation early in life that underlie permanent behavioral change expressed later in life. Crnic (1991) postulated that individual differences in the development of atypical behavior may be caused by common immunological stimuli that have uncommon effects on the biological basis of behavior.

UNCOMMON BIOBEHAVIORAL EFFECTS OF IMMUNE STIMULI: IMPLICATIONS FOR DEVELOPMENTAL PSYCHOPATHOLOGY?

In a series of studies, we attempted to extend the basic ideas forwarded by Crnic (1991) by exploring sources of individual differences in the uncommon biobehavioral effects of common immune stimuli. It was anticipated that by doing so, important clues would be revealed that would contribute to a more general understanding of individual development, microevolution, and the development of psychopathology. The studies employed a well-established animal model that represents the major dimensions of atypical social development: internalizing and externalizing behavior problems. The model system, developed by Robert Cairns at the University of North Carolina at Chapel Hill, involves two lines of mice (ICR) that have been selectively bred for differences in social interaction patterns and a control line of mice bred without selection for behavior (for details, see R. B. Cairns, MacCombie, & Hood, 1983). Selection for breeding was based on the social isolation-induced aggressive behavior of adult males assessed in a 10-minute observation of dyadic social interaction. Within a few generations, the program resulted in a high-aggressive and low-aggressive line. Selective breeding was continued for 30 generations. Presently, the lines are maintained by Kathryn Hood at the Pennsylvania State University without further selective pressure.

The model has several advantages that make it valuable for testing hypotheses about the uncommon effects of common immune stimuli on biobehavioral outcomes. There are demonstrated sensitive periods for early experiences that influence later social behavior (B. D. Cairns, Hood, & Midlam, 1985; Hood & Cairns, 1989) and established procedures for assessing adult levels of social behavior (R. B. Cairns, Garipey, & Hood, 1990; Hood & Cairns, 1988). At 44 to 46 days of age, animals are observed in a dyadic test during the dark period of the diurnal cycle. Subjects are placed into a rectangular Plexiglas chamber (20 × 21 × 31 cm), with a metal barrier dividing the chamber in half. An unfamiliar

same-age male is placed in the other half. After a 5-minute habituation period, the barrier is removed and the mice are allowed to interact for 10 minutes. Dyadic behaviors are videotaped under dim red light. Social behaviors are coded from videotapes in 120 5-second sequential blocks of the 10-minute test period. Within each 5-second period, an observer scores the presence of the following behaviors: attacks (a vigorous lunge accompanied by biting and wrestling); attack latency (the number of seconds until the first attack by the subject); behavioral immobility/freeze (subject does not move for at least 2 seconds); social reactivity/startle (a startle response, jumped or kicked with the hind leg in response to mild social stimulation, such as a sniff or groom from the partner); and social exploration (sniffing, climbing on, or grooming the social partner). Dependent measures are compiled as the number of 5-second periods in which a behavior occurred, with a maximum score of 1 for each behavior in each 5-second period.

A series of studies by John Pettito and colleagues show line differences in immune responsiveness at the cellular level. When challenged with 3-methylcholanthrene, 100% of the mice from the socially inhibited/low-aggressive line developed tumors, compared to only 44% of the high-aggressive line animals. The line differences were extended to include NK cell and T and B cell responsiveness *in vitro*. Compared to aggressive mice, low-aggressive mice had significantly lower T cells, lower proliferative responses to concanavalin A, lower IL-2 and interferon gamma production, and lower NK cell activity (Pettito, Lysle, Garipey, Clubb, et al., 1994; Pettito, Lysle, Garipey, & Lewis, 1992, 1994). Pettito speculates that this association may be due to a genetic linkage between subsets of genes involved in determining these complex behavioral and immunological traits (Pettito et al., 1999).

Individual Differences

In an attempt to complement Pettito et al.'s work, D. A. Granger, Hood, et al. (1997) explored the possibility that genetic-developmental differences in social behavior are associated with differences in the biobehavioral effects of induced illness in adult animals. The expectation was that animals from the high-aggressive line would show a more robust proinflammatory response than the low-aggressive line mice. Adult males from high- and low-aggressive behavior lines were injected with endotoxin (LPS: 0.25 mg/kg, 1.25 mg/kg, or 2.5 mg/kg) or saline. Body temperature, weight, and locomotor activity were monitored before and 8 and 24 hours after injection. Twenty-four hours after injection, social behaviors were assessed in a 10-minute dyadic test, and tissue (spleens and hypothalami) were collected. As hypothesized, high-aggressive line males had a

lower threshold to endotoxin-induced effects on body temperature, weight loss, spleen weight, hypothalamic norepinephrine, and corticosterone than did males from the low-aggressive line. In the high-aggressive line only, social reactivity (startle response to mild social investigation) increased, and attack frequency and latency to attack decreased for endotoxin-treated compared to saline-treated mice. Table 17.2 presents bivariate correlations among the biobehavioral effects of endotoxin by selected line. Noteworthy is the fact that endotoxin-induced differences in activation of the immune response (crudely estimated here by spleen weight) and HPA axis (i.e., corticosterone) were significantly associated with activity levels, weight, and body temperature 8 and 24 hours postinjection in the high-aggressive but not low-aggressive line mice. The selected line (genotype) \times endotoxin treatment (environment) interactions demonstrate that genetic-developmental differences in social and aggressive behavior may indicate the extent to which immune stimuli function as biobehavioral stressors.

In a companion set of studies, we attempted to link the time course of the biobehavioral effects of endotoxin to proinflammatory cytokine (IL-1 β) production (D. A. Granger, Hood, & Banta, 2000). In a between-subjects de-

sign ($N = 120$; 5 per design cell), adult male mice from the high- and low-aggressive lines were administered endotoxin (1.25 mg/kg) and social behavior was assessed (as described earlier) and serum harvested (immediately following cervical dislocation via cardiac puncture) at 12 time points (0.5 to 6, 18, and 24 hours) postinjection. As in the earlier study, in contrast to low-aggressive line mice, high-aggressive line mice showed endotoxin-induced reduction in attack frequency, an increase in attack latency, more pronounced increases in behavioral immobility, and more socially reactive behaviors. As can be seen in Figure 17.7, high-aggressive mice produced IL-1 β more quickly and at higher levels than did low-aggressive mice. Although there was not a significant line difference in the production of corticosterone, endotoxin-related differences in levels of IL-1 β , corticosterone, and behavior change were positively associated in the high-aggressive line only. For example, Figure 17.7 illustrates that the increases in IL-1 β , corticosterone, and socially reactive behavior postinjection were closely coordinated in time in the high-aggressive but not the low-aggressive line. Because an endotoxin dose of 1.25 mg/kg is on the high end of the scale, a follow-up experiment confirmed that the basic finding—the line difference

TABLE 17.2 Bivariate Correlations among the Biobehavioral Effects of Endotoxin in Adult Male Mice Selectively Bred for Differences in Social Behavior

Notes: Data were averaged across endotoxin dose. Activity, weight, and temperature scores represent percent change from baseline (preinjection) levels at 8- and 24-hours postinjection. Serum corticosterone (CORT) levels and social behaviors were assessed 24 hours postinjection. ^a $p < .001$ (all dfs = 19, two-tailed tests); ^b $p < .01$; ^c $p < .05$; ^d $p < .06$. *Source:* From "Effects of Peripheral Immune Activation on Social Behavior and Adrenocortical Activity in Aggressive Mice: Genotype-Environment Interactions," by D. A. Granger et al., 1997, *Aggressive Behavior*, 23, pp. 93–105.

Figure 17.7 Time course effects of endotoxin (1.25 mg/kg) for Interleukin-1 β and socially reactive (startle) behaviors are correlated, but distinctly differ in mice selectively bred for high versus low levels of aggressive behavior. *Source:* From *Individual Differences in Endotoxin Effects on Social Behavior and Interleukin-1 β* , by D. A. Granger, K. E. Hood, and M. B. Banta, 2000, unpublished manuscript, University Park, Pennsylvania State University.

in IL-1 β production—was evident even at a fivefold lower endotoxin dose (0.25 mg/kg).

Taken together with the findings with parallel lines of mice (e.g., Pettito et al., 1999; Pettito, Lysle, Garipey, Clubb, et al., 1994; Pettito, Lysle, Garipey, & Lewis, 1992, 1994), these data suggest that the observed pattern may in part be due to line differences in peripheral proinflammatory cytokine production. Clearly, the possibility cannot be ruled out that there may be line-differential CNS or HPA axis sensitivity to the afferent signals of cytokines, to other acute phase proteins, or to endotoxin itself. However, the lack of a corticosterone difference

between lines in response to endotoxin suggests the last possibility is unlikely.

In the next experiment, the possibility of a line difference in sensitivity to proinflammatory cytokines was examined. Endotoxin was removed from the equation, and the direct effect of IL-1 β on biobehavioral outcomes was tested. Adult males from the high- and low-aggressive lines were administered a standard dose of IL-1 β IP (0.25 to 1.0 ug/ml) or saline. Consistent with Pettito’s findings, high-aggressive line mice showed higher circulating levels of IL-6 than did low-aggressive mice (see Figure 17.8), but the difference was most pronounced at the highest (1.0 ug/mL) IL-1 β dose. As can be seen in Table 17.3, in the high-aggressive line, individual differences in IL-6 levels in response to IL-1 β injection were associated with higher levels of corticosterone, temperature loss, and behavioral immobility and reduced social exploration in observed social interactions.

The mechanisms responsible for the apparent linkage between these behavioral traits and immune function are unclear. Pettito and colleagues (1999) raise two possibilities: that the association between selective line and immune

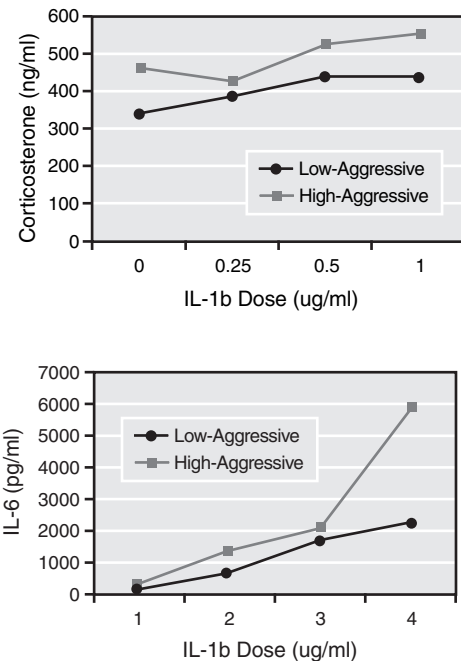

Figure 17.8 Exogenous administration of Interleukin-1 β (ug/mL) induces Interleukin-6 and corticosterone differently in adult male mice selectively bred for high versus low levels of aggressive behavior. *Source:* From *Individual Differences in Endotoxin Effects on Social Behavior and Interleukin-1 β* , by D. A. Granger, K. E. Hood, and M. B. Banta, 2000, unpublished manuscript, University Park, Pennsylvania State University.

TABLE 17.3 IL-1 β -Induced Circulating Levels of Interleukin-6 Are Correlated with Measures of HPA Axis Activation and Social Behavior

Hood, and M. B. Banta, 2000, unpublished manuscript, University Park, Pennsylvania State University.

function may be due to a genetic linkage between subsets of genes involved in determining these complex traits, or that these results may represent a fortuitous association that occurred during selective breeding. There is some independent evidence that the aggression-immunity link may not be random. Experimental nonhuman primate studies (*Macaca Fascicularis*) reveal that changes in cellular immunity in response to the stress of repeated social reorganization are associated with individual differences in aggressive behavior (Cohen et al., 1997), and high-aggressive monkeys have higher lymphocyte counts than low-aggressive monkeys (Line et al., 1996).

In the largest study to date of the relationship between aggression and immunologic processes in humans, D. A. Granger, Booth, and Johnson (2000) evaluated two conflicting models: a positive association stemming from an adaptive mechanism protecting aggressive individuals from increased exposure to immune stimuli and a negative association due to potential immunosuppressive effects of high testosterone levels. The models were tested using enumerative measures of cellular and humoral immunity in a sample of 4,415 men ages 30 to 48 who were interviewed and underwent a medical exam. The findings provided clear evidence in support of the first model and failed to support the second. Analyses revealed positive (and curvilinear) associations between aggressive behavior and enumerative measures of helper/inducer and suppressor/cytolytic T lymphocytes and B lymphocytes. More specifically, men with very high levels of aggressive behavior did not show correspondingly higher numbers of circulating lymphoid

cells. In contrast, the relationship was robust for men who exhibited moderate levels of aggressive behaviors. The aggression-immunity relationship was independent of testosterone level, age, body mass, depression, current health status (e.g., colds, injuries, sexually transmitted diseases, and general health symptoms), and negative health behaviors (tobacco, alcohol, and drug use and sexual promiscuity) and was most pronounced for helper/inducer T cells. There was no association between testosterone and any immune measure. It may be noteworthy that the aggression-immunity association was strongest for the numbers of T helper cells (CD4), cytolytic T cells (CD8), and B lymphocytes. As noted earlier, to a large extent this subset of lymphoid cells determines the initiation, magnitude, and duration of specific cellular immune responses. The functional responsibilities of CD4 cells include the activation of B cells, secretion of cytokines that regulate intercellular communications among T lymphocytes, and potentiation of the cytolytic activity of natural killer cells. CD4 cells facilitate both humoral and cellular branches of specific immunity and thus affect the immune response to both extracellular (bacteria) and intracellular (e.g., malignant or virally infected cells) antigens. The functional significance of B cells includes specific antigen recognition, antigen presentation, antibody production, and maintenance of immunologic memory.

Although these findings focus attention on aspects of specific cell-mediated immunity, there is scant empirical evidence to suggest which of the many physiological pathways possibly responsible for the association should receive priority research attention. As noted earlier, even among the best-developed animal models, the source of the link between aggression and immunity remains unknown. Research focused on elaborating the nature and sources of the apparent aggression-lymphocyte link would seem to be the next logical step to begin the process of ruling out the many alternative hypotheses. However, in our opinion, it would be shortsighted to focus this effort on aggression exclusively. No research to date has ruled out the possibility that other behavior profiles may be associated with the uncommon effects of common immune stimuli.

Developmental Effects

Among the enduring issues in developmental psychobiology are the origins of individual adaptations to changing environments and how these influences are integrated with maturational processes to produce differences in social behavior (Cicchetti & Dawson, 2002). In general, it has been proposed that developmental integration occurs in response

to environmental forces that are predictable and omnipresent but often nonobvious. In this developmental integration, very early stimulation may lead to differences in later life in the threshold or sensitivity of behavioral and physiological responsiveness to challenge (Hood, Dreschel, & Granger, 2003).

To explore individual differences in the developmental consequences of early immune stress, D. A. Granger, Hood, Ikeda, Reed, and Block (1996) evaluated neonatal immune stress and differences in social expression at adulthood. Neonatal male mice from the high- and low-aggressive lines were administered saline or 0.05 mg/kg endotoxin at age 5 or 6 days. There was a transient endotoxin-induced reduction in the growth rate (72 hours after injection) of the neonates from the high-aggressive line only. At adulthood, social behaviors were observed in the dyadic test (as in the earlier studies). As young adults, endotoxin-treated males show more socially reactive behavior (startle responses) to a novel social partner's contact compared to saline controls. For the high-aggressive line only, endotoxin treatment increased behavioral immobility, decreased attack frequency, and increased attack latency compared to same-line saline-treated controls. Within 20 minutes of the conclusion of the dyadic test, sera and hypothalmi were harvested. Neonatal endotoxin-treated males from the high-aggressive line as adults show decreased levels of hypothalamic CRF. The effects of endotoxin exposure in early life on socially reactive behavior in later life were associated with endotoxin-induced individual differences in CRF levels in the high-aggressive but not low-aggressive line mice. These findings suggest that variation in the expression of socially inhibited behaviors in later life may be partially explained by differential sensitivities to the effects of exposure to immune stimuli in early life.

These developmental findings are consistent with the multiple studies described earlier that show adult males from the high-aggressive line are intrinsically more immunologically reactive to endotoxin compared to males from the low-aggressive line. In a follow-up experiment, it was confirmed that early in development (age 6 to 8 days), males from the selected lines were capable of producing IL-1 β in response to endotoxin. Neonates ($N = 100$) were injected IP with saline or 0.5, 0.25, or 1.25 mg/kg endotoxin. Two hours postinjection, trunk blood was collected and frozen for later assay. To ensure sufficient test volume, whole blood samples were pooled across two male siblings. There was a highly significant main effect of endotoxin dose on IL-1 β , with means (and standard deviations) of 2.62 pg/ml (4.73), 16.71 pg/ml (21.74), and 87.49 pg/ml (61.03), for the saline, 0.25 mg/kg, and 1.25 mg/kg condi-

tions, respectively. The variation within dose conditions was sufficiently large that line differences in IL-1 β were not evident.

Hood et al. (2003) note that these convergent findings impel a consideration of the biobehavioral pathways through which these effects are realized. Are alterations in social development a direct result of immune stimulation, perhaps mediated by the HPA axis? A complementary hypothesis is that concurrent changes in dam-pup interactions produced by pup immune stimulation and related changes in pup behaviors might be reflected by changes in dam's behavior, which then may impact pup's behavior in a circular reaction over the course of early development to bring about long-term changes in social expression.

The Role of the Social Environment: Early Maternal Caregiving

In mammalian species, early development is embedded in the social context of maternal caregiving (Hofer, 1994; Krasnegor & Bridges, 1990). Differences in maternal responsiveness during interactions with neonates are sufficient to alter adult offspring behaviors in important ways. A major hypothesis is that the developing HPA axis in young animals is regulated by maternal behavior (Hofer, 1987; Levine, 1994). Much of the research on this question employs a handling manipulation—a brief daily removal of young from the maternal cage sufficient to activate maternal behaviors, especially licking and grooming of pups when they are returned to the dam. The general finding is that increased maternal licking and grooming promotes in later life a more efficient HPA response to severe stress and decreased HPA response to moderate stress, such as a novel environment. In rats, handled offspring develop faster and show earlier maturation of the HPA system. As adults, handled offspring show increased resistance to stress and disease and reduced fear-related behaviors. These favorable response patterns persist throughout the life span (Meaney, Aitken, Bhatnagar, Van Berkel & Sapolsky, 1988).

Immune stimulation, by contrast, may produce a different pattern of developmental effects. After early handling, the adult HPA axis is less responsive to stress; however, after endotoxin exposure, the HPA axis is more responsive (Shanks et al., 1995). This pattern is similar to the effects of prolonged maternal separation (deprivation) in rats, which produces lifelong HPA hyperresponsiveness to stress and associated vulnerabilities (Plotsky & Meaney, 1993).

Experimental manipulation of pups may change the stimulus value of pups for dams and thus may constitute another route of developmental effects (Hood et al., 2003).

Two lines of evidence suggest that line-specific maternal responsiveness to endotoxin-treated pups may contribute to differences in early endotoxin exposure effects later in life. Shanks and colleagues (1995, p. 382) reported anecdotal evidence of changes in dam-pup interactions following endotoxin administration to neonates: "At 3–4 hours postinjection, the dam was consistently off the nest, and this persisted until about 8 hr following treatment." Another source of variation in dam-pup interactions derives from systematic individual differences in dam or pup characteristics. Two studies using lines of mice that are related to those in the present report show line differences in maternal behaviors in a daily handling paradigm (Garipey, Nehrenberg, & Mills-Koonce, 2001) and in observations of undisturbed litters (Rodríguez, Garipey, & Jones, 1998), with different patterns of line differences in the two observation protocols. Garipey et al. showed, for example, that dams from the high-aggressive line are naturally more active (more licking, handling of pups, social contacts) in maternal caregiving than are dams from the low-aggressive line.

The evidence suggests several developmental pathways for the effects of early immune stimulation on later social expression. The first model specifies a physiological pathway of endotoxin-immune-HPA effects that directly alter behavior by intrinsic line differences in susceptibility to endotoxin. A second model proposes a possible pathway through the social-behavioral milieu of early development. Differences in maternal responsiveness to endotoxin-treated pups may contribute to or may completely constitute the pathway of early endotoxin effects on social development. Alternatively, differential susceptibility of pups to endotoxin effects may alter pups' contributions to dam-pup interactions, with consequent changes in the early social milieu (Hood et al., 2003). Finally, a third model proposes there may be combinations of these factors that

produce development change. An example would be easily disrupted dams paired with more susceptible pups resulting in ineffective maternal care and associated effects.

In a recent report, D. A. Granger, Hood, Dreschel, Sergeant, and Likos (2001) directly addressed one of these models. The origins of individual differences in social behavior were examined in relation to early stress (immune challenge) and the social milieu (maternal behavior) using the genetic-developmental model. The study examined the persistence of line differences in the developmental effects of induced illness early in life under two conditions of maternal care (see Table 17.4). Neonatal mice from the high- and low-aggressive selectively bred lines received saline or 0.05 mg/kg LPS on day 5 or 6, as before. Litters were reared either by their line-specific biological dam or by a foster dam from a line bred without selection. As before, adult social behaviors were assessed in a dyadic test. If the first model is correct, then regardless of the maternal caregiving environment, high-aggressive line mice will show more pronounced developmental effects of immune challenge early in life than low-aggressive line mice. If the second model is correct, then effects of the early social milieu (being reared with the biological dam or being fostered to a control-line dam) will appear. A third possibility is that both sources of individual (selective breeding) and environmental (maternal caregiving) differences will contribute to patterns of adult social expression after early immune stress.

As in previous studies, mice from the high-aggressive line showed more developmental sensitivity to immune challenge than mice from the low-aggressive line. As adults, endotoxin-treated mice from the high-aggressive line have lower levels of aggressive behavior, longer latency to attack, and higher rates of socially reactive and inhibited behaviors compared to saline controls (see Table 17.5).

TABLE 17.4 Predictions on Developmental Integration of Early Immune Exposure: Effects on Adult Social Behaviors

Family of Origin	Maternal Caregiving	Intrinsic Sensitivity to Immune Challenge	Adult Social Behavioral Outcome
High-aggressive Low-inhibition	Low caregiving	More sensitive	Lower externalizing Higher internalizing
Low-aggressive High inhibition	High caregiving	Less sensitive	Higher internalizing

Note: Externalizing behaviors in the model include attack frequency and latency. Internalizing behaviors include social inhibition and social reactivity. Reprinted from "Developmental Effects of Early Immune Stress on Aggressive, Socially Reactive, and Inhibited Behaviors," by D. A. Granger, K. E. Hood, N. A. Dreschel, E. Sergeant, and A. Likos, 2001, *Development and Psychopathology*, 13, pp. 599–610.

TABLE 17.5 Differential Effects of Endotoxin Exposure by Selectively Bred Line: Mean (and Standard Deviations) for Social Behaviors

Selected Line Neonatal Exposure	Low-Aggressive		High-Aggressive	
	Saline (n = 18)	Endotoxin (n = 21)	Saline (n = 22)	Endotoxin (n = 19)
Attack frequency	00.00 (00.00)	00.00 (00.00)	48.86 (17.87)	32.68 ^a (22.32)
Attack latency	—	—	28.41 (28.09)	137.37 ^a (197.46)
Behavioral immobility	21.17 (12.97)	25.81 (16.70)	0.68 (1.78)	4.95 ^a (6.68)
Social reactivity	0.72 (0.89)	2.71 ^b (3.20)	1.54 (2.72)	6.26 ^b (8.32)
Social exploration	71.00 (18.69)	67.05 (18.74)	16.68 (14.11)	26.74 (24.45)

Note: ^a $p < .01$; ^b $p < .05$; T-tests (two-tailed) comparing neonatal endotoxin versus saline exposure conditions within selected line. The unit of measurement for attack latency is the number of 5-s observation periods to first attack. All other behaviors are scored as the number of 5-s periods in which the specific behavior was observed. Reprinted from “Developmental Effects of Early Immune Stress on Aggressive, Socially Reactive, and Inhibited Behaviors,” by D. A. Granger, K. E. Hood, N. A. Dreschel, E. Sergeant, and A. Likos, 2001, *Development and Psychopathology*, 13, pp. 599–610.

The data support a robust pattern of individual differences, with variation in the developmental effect of early immune challenge that is systematically related to preexisting individual differences in aggressive behavior. Beyond these confirmatory observations, several new findings are noteworthy. The systematic developmental effects within the high-aggressive line are relatively unaffected when the social environment of early rearing is held constant by fostering animals to mothers from a control line of mice. By contrast, within the low-aggressive line there is only one behavior that is sensitive to early immune challenge (social reactivity), and that effect is strongly dependent on pup-dam interactions with the biological mother. Moreover, the effects of rearing environment are markedly different between the lines. In the high-aggressive line, there are multiple effects of endotoxin and only a single effect of rearing environment. In the low-aggressive line, there are multiple behaviors affected by fostering and only a single behavior influenced by endotoxin, in interaction with the fostering conditions. That the effects of endotoxin are robust in the high-aggressive line regardless of rearing condition rules out line differences in maternal behavior as the primary source of the development effect. However, there remains the possibility that high-aggressive pups treated with endotoxin are eliciting different behaviors from their own dams and from foster dams, compared to pups treated with saline.

In a design that complements this study, Hood et al. (2003) rigorously examined whether differences in mater-

nal responsiveness during interactions with endotoxin-treated pups might contribute to endotoxin effects on social development. Based on the findings reported earlier (see Table 17.5), it was hypothesized that when intrinsic differences in immune responsiveness are extreme (as with individuals from the high- versus low-aggressive lines), maternal responsiveness to endotoxin-treated (“sick”) pups may have little or no influence on social behavior outcomes later in life. The social environment’s capacity to influence the developmental outcome under these conditions may be orders of magnitude less than the contribution made to the outcome by the intrinsic differences in immunologic reactivity (D. A. Granger et al., 2001). Alternatively, when intrinsic differences in immunologic reactivity are not as extreme (or within the normal range as depicted in Figure 17.5), the ontogenic process should be more open to the influence of differential experience with social environmental processes. Hood et al. examined the latter possibility. Figure 17.9 presents an overview of this complex design. Neonatal mice bred without selection for behavior or differences in immune reactivity were fostered to dams from either the high- or low-aggressive lines of mice (because they show distinct differences in maternal caregiving behaviors; Garipey et al., 2001; Rodriguiz et al., 1998) or dams from a control line bred without selection. Repeated naturalistic observations of maternal behavior on postnatal days 2, 4, 5, 6, and 8 were conducted. Scan-sampling procedures were implemented by observers blind to dam line and endotoxin treatment conditions to record the following

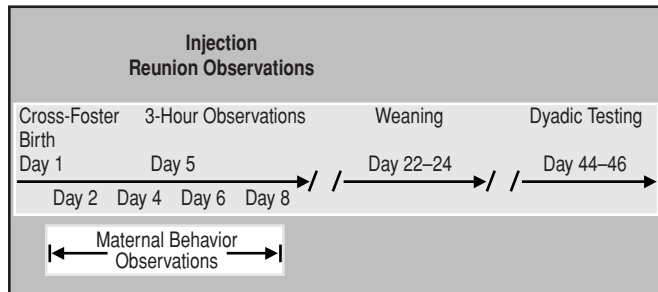

Figure 17.9 Developmental research design: time line of fostering, injections, and assessments. *Source:* From “Maternal Behavior Changes after Immune Challenge of Neonates with Developmental Effects on Adult Social Behavior,” by K. E. Hood, N. Dreschel, and D. A. Granger, 2003, *Developmental Psychobiology*, 42, pp. 17–34.

maternal behaviors: off-nest (dam off nest and not in contact with pups), nursing (dam in a nursing posture), lick (dam licking pups with mouth or tongue movements), and handle (dam nosing, touching with paws or moving pups). To provide a special focus on licking of pups by dams (this behavior is low-frequency), an additional event sampling procedure was implemented on each observation day (see Hood et al., 2003, for detail). As in the earlier studies, on postnatal day 5, neonates were administered saline or 0.05 mg/kg endotoxin. However, this time two observation periods on postnatal day 5 were of interest. Reunion episodes were observed to capture the immediate reactions of dams to pups that had been removed from the nest after handling and treatment with endotoxin. For 5 minutes after the pups’ return, observers recorded maternal behavior (i.e., latency to first retrieve of a pup, latency to last retrieve, off-nest, touching or handling a pup, licking, and nursing). Simultaneously, ultrasonic vocalizations (USV) from the pups as an index of individual differences in their solicitation/response to the social environment during the reunion episode. Additional scan and event sample observations of maternal behavior were recorded 3 hours postinjection, when the illness response of pups to endotoxin was expected to be at peak intensity.

Result showed for the first time (to our knowledge) that the early maternal caregiving environment may influence the effects of early illness on social development. Consistent with the time course of endotoxin-induced illness, we observed dramatic but temporary effects on maternal caregiving. Dam responsiveness to induced pup illness was related to later social development, with changes in prosocial behaviors (social exploration) and antisocial behaviors (attack frequency and latency) that occur in different patterns in pups reared in the three dam lines. The immediate im-

part of endotoxin treatment on dam-neonate interactions is evidenced by slower retrieval of pups, more time off-nest, less contact with pups, and fewer USVs from pups. At the peak of pups’ induced illness, 3 or 4 hours after endotoxin treatment, maternal care is restored and enhanced, with more licking and less time off-nest for endotoxin-treated than saline-treated pups. By days 6 and 8 (24 and 72 hours postinjection), endotoxin effects on maternal behavior are not evident. Similarly, weights at weaning (day 22 to 24) show no effect of endotoxin treatment. As expected, line differences in maternal responsiveness were pronounced. More important, males exposed to endotoxin early in life showed changes in adult social behaviors that depended on foster dam line as well as individual differences in maternal responsiveness.

This study highlighted the potential usefulness of a social-contextual analysis for understanding early experience effects (e.g., Cicchetti & Richters, 1997). Specifically, it showed that when intrinsic individual differences in immune reactivity are within the normative range, maternal responsiveness to stressed neonates can ameliorate the social-developmental effects of early illness (Hood et al., 2003). Collectively, this series of studies (D. A. Granger et al., 1996, 2001; Hood et al., 2003) demonstrate that nonobvious but omnipresent features of the physical environment early in life, such as antigenic load, may interact with intrinsic differences in immunologic reactivity and the social environment to determine individual social developmental outcomes. The findings support Crnic’s (1991) proposal that individual differences in development may be caused by common immune stimuli that have “uncommon effects” on the psychobiological basis of behavior. They extend Crnic’s observations by specifying factors that influence susceptibility, including intrinsic differences in social behavior, immunologic reactivity, risk of exposure, and the capacity of the early caregiving environment to facilitate recovery.

CONCLUDING COMMENTS AND FUTURE RESEARCH DIRECTIONS

Contemporary developmental theorists place behavioral adaptation in a pivotal position with respect to the bidirectional nature of environmental and biological influences on individual development. Cognitive-behavioral responsiveness to environmental events is thought to mediate or moderate the impact of such events on rapid (e.g., hormones, neurotransmitters) and slower acting (e.g., genetic activity) biological systems (Gottlieb, 1992). Subsequently, the effects of these biological systems manifest as adjustments

in behavioral organization or responsiveness, or both. The functional and integrative integrity of the reciprocal influences among these systems is considered essential for optimal development (Cicchetti & Dawson, 2002). For instance, these processes enable individuals to continuously adapt to the ever-changing topography of social ecological landscapes, as well as appropriately engage the social context during life periods characterized by rapid acquisition of new skills and abilities (e.g., infancy, toddlerhood, adolescence).

It seems reasonable that cytokines may affect developmental plasticity via their impact on biobehavioral processes that set the stage for successful behavioral, emo-

tional, social, and cognitive adaptation. As noted, there is unequivocal evidence that cytokines restrict the range of adaptive behaviors in several domains and may induce some maladaptive behavioral and psychological states. These cytokine-induced changes may potentiate the impact of environmental events on stress-responsive biological systems. For instance, cytokine effects may limit the behavioral surface's ability to effectively moderate the impact of environment challenge on HPA axis and sympathetic nervous system activation. Alternatively, cytokine-induced psychological states (maladaptive coping strategies, emotion regulation, cognitive slowing) may potentiate the responsiveness of environmentally sensitive

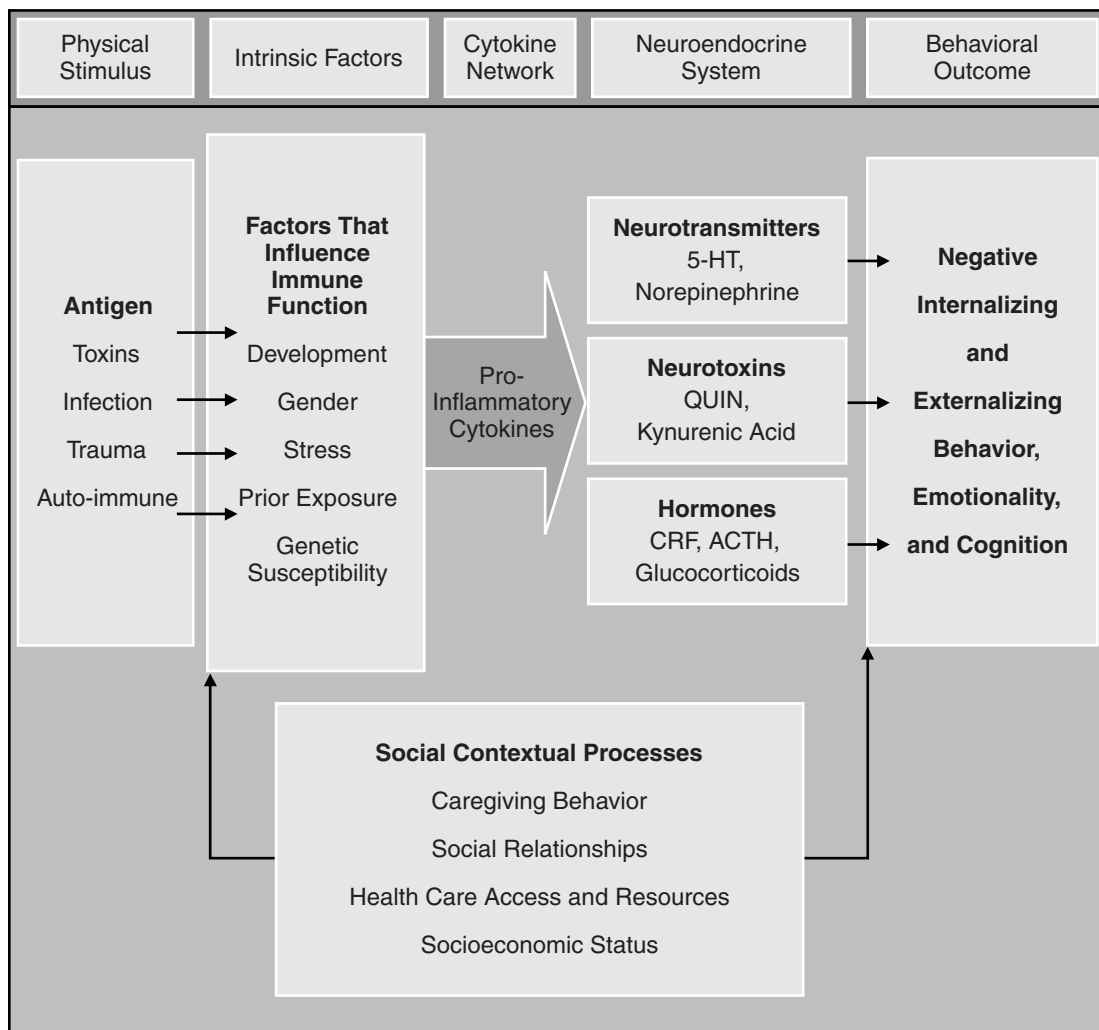

Figure 17.10. Theoretical model of interacting processes contributing to individual differences in the developmental effects of the activation of the cytokine network. *Source:* From “Developmental Psychoneuroimmunology: The Role of Cytokine Network Activation in the Epigenesis of Developmental Psychopathology” (pp. 293–323), by D. A. Granger, N. A. Dreschel, and E. A. Shirtcliff, in *Neurodevelopmental Mechanisms in Psychopathology* by D. Cicchetti and E. Walker (Eds.), 2003, New York: Cambridge University Press.

biological systems. Still another possibility is that cytokine effects at the behavioral surface level restrict individual opportunities to engage contexts that nurture social, cognitive, or behavioral development. For instance, cytokine-induced social and defensive withdrawal or cognitive slowing would limit experiences in ways that would preclude vicarious or trial-and-error learning, parent-child interactions, or peer relationships.

In the field of child development, etiologic factors determining vulnerability to specific atypical developmental outcomes have for the most part consistently eluded detection. Even when the range of potential causal factors has been narrowed, it is clear that individual differences in the expression of their effects are the rule rather than the exception. Given this somewhat discouraging state of our knowledge, it is not surprising that theorists commonly assume that atypical developmental outcomes represent the final common pathway of multiple independent and interacting factors. This perspective has proven useful for some purposes (i.e., identifying the range of prospective causal factors) but has not necessarily resulted in progress toward defining the nature of cause and effect.

We forward an alternative perspective: that a common set of biobehavioral processes may be responsible for causing subtle deviations in biological and behavioral plasticity. The effects of this common initial pathway may modify developmental processes impacting a range of atypical developmental outcomes. It follows that individual differences in the nature of these effects would be shaped by person factors (i.e., polygenic control of the immune response, central nervous system sensitivity to cytokines, critical periods of the development of the neuroendocrine-immune network), environmental factors (i.e., frequency, duration, or timing of exposure to immunologic stimuli), as well as social processes.

A theoretical model representing the possible direct and indirect pathways between dysregulation of the cytokine network and developmental psychopathology is presented in Figure 17.10. At least five levels of analysis are relevant to understanding individual differences in the uncommon effects of common immune stimuli: (1) features of the physical environment or socioeconomic factors that increase risk or exposure to immune stimuli (e.g., population density, hygiene, water and food quality, health care access or quality); (2) psychological factors that limit individuals' understanding or perceptions of susceptibility, severity of consequences, and risk or threat of exposure to antigens; (3) physiological predispositions or states that affect the synthesis of immune-derived molecules or that influence the sensitivity of target organs and tissues; (4) the capacity

of the social environment to facilitate or disrupt recovery once a susceptible individual has been exposed; or (5) the competence of the individual at risk to elicit assistance and support from the social environment. Adopting this biosocial model leads to testable hypotheses at several levels of analysis.

It is our expectation that the findings of studies that integrate this perspective and these psychoneuroimmunologic concepts into developmental science may engender strong inferences focused on explaining the nature of causation rather than simply describing phenomena and their correlates. To adequately investigate this model, studies are needed that employ prospective longitudinal designs and focus on the link between the activity of cytokines and the onset, changes, and continuities of atypical behavioral and biological function. Studies to elaborate these uncommon developmental effects in the context of experiments of nature (Cicchetti, 2003), such as childhood immunizations, early childhood infections or inflammatory diseases, and in special populations at high risk of exposure to immune stimuli early in life would seem an appropriate next step.

CONCLUDING COMMENTS AND FUTURE DIRECTIONS 733

REFERENCES 735

The transitional, formative, and malleable nature of adolescence makes it arguably the most important period of development for the study of developmental psychopathology. As a transitional period, adolescence is marked by rapid and dramatic intraindividual change in the realms of biology, cognition, emotion, and interpersonal relationships and by equally impressive transformations in the major contexts in

The development of the framework described in this chapter was supported by the John D. and Catherine T. MacArthur Foundation Research Network on Psychopathology and Development under the leadership of David Kupfer. The authors express their deep appreciation to the MacArthur Foundation and to all the members of this network for their contributions to our thinking about development and psychopathology in the transition to adolescence. The ideas expressed in this chapter are collaborative, with all authors contributing to writing the chapter. The first author coordinated the preparation of this chapter; all other authors are listed alphabetically.

which children spend time: the family, the peer group, and school. These transformations alter individual strengths and vulnerabilities and present both opportunities and challenges that require adaptation on the part of the developing adolescent. For a significant proportion of adolescents, the interaction between these changes in intraindividual functioning and changes in context result in the emergence of some emotional and behavioral problems. Notably, many behavioral and affective problems, such as substance abuse and disordered eating, are seldom or rarely seen before adolescence, and others, such as Major depression and bipolar illness, show a dramatic increase in prevalence during this period. For many more adolescents, the period is one of experimentation with risky activity, behavior that, though not formally considered psychopathology, nonetheless increases morbidity and mortality considerably.

As a formative period, adolescence is important to the study of developmental psychopathology because after this

maturational interval, some patterns of emotional and behavioral difficulty may become more difficult to alter. For reasons not yet understood, there appears to be relatively more consolidation of psychopathology in adolescence than in earlier periods. Prospective longitudinal studies suggest that the majority of chronic and recurrent psychiatric problems that afflict adults have begun by the end of adolescence. Indeed, the initial manifestations of affective disturbance, antisocial behavior, and substance abuse emerge much less frequently in adulthood than in previous developmental periods and are generally preceded by problems in these or other domains during adolescence. This applies both to problems with behavior, as in the disruptive behavior disorders, and to problems with emotion regulation, as in the mood and anxiety disorders (Moffitt & Caspi, 2001; Pine, Cohen, Gurley, Brook, & Ma, 1998). Adolescence is also critical in setting lifestyle trajectories with enormous long-term implications for adult health. These trajectories include early patterns of behavior in the realms of exercise; nutrition; the use of tobacco, caffeine, alcohol, and other mood-altering substances; and sleep and other health habits. Adolescence is the period for establishing the foundation for advanced education, major life roles, relationships, and working toward long-term productive goals. Accordingly, adolescence is an *important period for the development of preventive interventions designed to head off the development of more serious psychopathology in adulthood.*

Finally, despite its formative nature, adolescence is a period of malleability, or developmental plasticity. Patterns of neural connection among and between systems of emotion, motivation, and cognitive processes related to the pursuit of long-term goals undergo a natural reorganization during adolescence. For example, the onset of puberty is associated with biologically based changes in motivational and emotional systems linked to reproductive behavior in ways that contribute to the development of sexual and romantic interests. A second example is how the developing concept of *self* along with the cognitive abilities to imagine future versions of this self—and affective experiences of fears or excitement linked to tragic or heroic versions of the future self—emerge during adolescence. Early experiences in these domains not only influence youth in psychological and emotional domains, but also have an impact through brain-behavior interactions on the patterns of connections among neural systems.

As reviewed in a subsequent section of this chapter, there is also increasing evidence that maturational brain processes are continuing throughout adolescence (Dahl & Spear, 2004; Spear, 2000). For example, even relatively simple structural measures, such as the ratio of white to

gray matter in the brain, demonstrate large-scale changes into the late teenage years (Giedd et al., 1999; Sowell, Delis, Stiles, & Jernigan, 2001; Sowell, Trauner, Gamst, & Jernigan, 2002). The impact of this continued maturation on emotional, intellectual, and behavioral development has yet to be thoroughly studied, but the evidence for ongoing developmental processes and apparent plasticity of brain development in adolescence suggests that this period may present some unique opportunities for intervention (including cognitive-behavioral, psychopharmacological, and/or other psychotherapeutic treatments).

Furthermore, any discussion of developmental psychopathology in adolescence must also consider the broader historical context that suggests that adolescence in modern society may reflect a convergence of recent biological and social changes that together have greatly expanded this maturational interval. Most contemporary writers, including the present authors, define adolescence as the interval between the onset of puberty (ordinarily seen as the most important marker of the onset of the period) and the transition into adult roles (ordinarily seen as the most important marker of the period's conclusion). Both historical data and anthropological studies indicate that the mean age of sexual maturation in premodern societies was around 16 or 17 years—very close to the age at which young people began assuming the adult responsibilities of work and family formation. Thus, throughout most of human history, adolescence—the interval between the onset of sexual maturity and the assumption of adult responsibilities—was often only a few years in length.

More recently, however, the physical manifestations of puberty have been occurring at earlier ages, particularly among girls. At the same time, and especially in the most recent decades, the end of adolescence (taking on full adult roles and responsibilities) has been occurring at a relatively later time, with the prolongation of formal schooling and the extension of the adolescent's economic dependency on his or her family of origin. In the United States, for example, the *average* age of menarche (one of the final steps in pubertal maturation in girls) occurs at 12.5 years (Steinberg, 2005), but full entry into adult roles is delayed for the majority of the population until at least 20 years of age and often well beyond (Arnett & Tanner, in press). Thus, in most contemporary industrialized societies, many youth spend close to a decade with sexually mature bodies and reproductively activated brains prior to taking on adult roles or status.

This general expansion of the adolescent interval makes early adolescence in contemporary industrialized society a period of particular vulnerability for maturational

disjunctions among biologic, behavioral, and social processes. More specifically, this confluence of historical and individual changes in patterns of biological maturity, contextual demands, and contextual supports appears to have opened a window of risk for behavioral and emotional health problems for many young members of modern societies as they negotiate the transition from childhood to adolescence and from adolescence to adulthood.

Adolescence is therefore a period of heightened risk in general. However, some individuals are at greater risk than others. Children at greatest risk include those who enter this demanding transition already vulnerable, as well as those who become vulnerable during this challenging time (due to genetic predispositions and/or earlier adverse experiences), those for whom the disjunctions between developmental domains are greatest, those facing the greatest challenges during the transition, those with the least contextual support, and those with bad combinations of low resources and heightened genetic and/or developmentally acquired vulnerability. One of the most important goals of research on psychopathology in adolescence is to achieve a better understanding of the processes—and mechanisms—by which neurobiology, behavior, and context interact during this transition to create vulnerability and risk that for some individuals can spiral into significant long-term impairments and psychopathology.

On the other hand, risk does not inevitably lead to bad outcomes. Risk is a probability relating to a specific outcome of interest in a group or population; individual adolescents can manifest considerable resilience despite their status as members of a group at risk for negative outcomes. It is equally important to understand why other individuals navigate this interval of development quite successfully, to better understand patterns and processes of protection and resilience. An informative research agenda will thus need to focus both on mechanisms and on the trajectories of development during the adolescent transition, as well as preceding transitions. The adolescent transition may activate preexisting risk conditions—conditions that may reflect a cumulative “chain of risk,” divergence into a pathway of vulnerability, or the expression of a latent problem from an earlier critical period (Boyce & Keating, 2004)—or introduce new risks that are specific to this developmental period. Increasing our knowledge of these developmental processes is crucial to inform policies and programs aimed at improving the health and well-being of adolescents and the adults they will become. The very fact that multiple transformations are occurring in adolescence may provide windows of opportunity for

positive influence as well as windows of risk (see also Cicchetti & Rogosch, 2002).

Our goal in this chapter is to stimulate the development of a research agenda that will lead to identifying specific developmental processes for specific types of psychopathology in ways that can be used to leverage interventions. For example, a better understanding of the processes underlying changes in affect regulation during pubertal maturation may ultimately inform interventions targeted at children at high risk for developing a depressive disorder (such as those with a strong family history of depression, or individuals with symptoms of anxiety) *before* the development of a more serious disorder. In a similar way, a deeper understanding of the developmental processes and unique opportunities in this maturational interval can eventually inform a broad range of policies and programs designed to decrease vulnerability and risk and promote healthier adolescent development and increase resilience.

This chapter is organized as follows. In the first section, we offer several general observations about psychopathology in adolescence that have emerged from research over the past several decades and that motivated the development of the present heuristic approach. Rather than review research on the nature, antecedents, and developmental course of specific disorders, we emphasize overarching principles that apply across different types of psychopathology and serve as a basis for understanding what is unique about developmental psychopathology in adolescence. This discussion of broad principles is followed by a section in which we introduce a new framework for research on psychopathology in adolescence. Within this framework, the development of psychopathology in adolescence is linked to the convergence of specific biological, cognitive, and contextual factors characteristic of the adolescent decade. Following our overview of the framework, we examine several aspects of developmental and contextual change that occur in adolescence, with detailed sections on changes in brain structure and function; in arousal, motivation, and affect regulation; in the development of regulatory competence; and in the major contexts in which adolescents spend time. The chapter concludes with a call for new, interdisciplinary research that examines the interplay among neurobiological, psychological, and contextual influences on psychopathology in adolescence.

PSYCHOPATHOLOGY IN ADOLESCENCE: SOME GENERAL OBSERVATIONS

For centuries, the study of psychological maladjustment and the study of adolescent development have been inextricably

cably linked, both conceptually and empirically. Philosophers, clinicians, scientists, and virtually all observers of human behavior have long noted that adolescence is a period of special significance for the emergence or intensification of various forms of emotional and behavioral disorder, including many internalizing problems (e.g., depression, bipolar illness, eating disorders), externalizing problems (e.g., delinquency, violence), and addictive disorders (e.g., alcohol abuse and dependency, drug abuse and dependency). Although scholars may disagree about *why* adolescence is so important to the study of clinical phenomena, there is little dispute over whether it *is* important. Indeed, the list of clinical phenomena that are *not* in some way centrally associated with adolescence is probably shorter than the list of clinical phenomena that are. Nevertheless, controversy remains concerning the scope of these developmental trends. On the one hand, marked changes in the prevalence of clinically meaningful emotional and behavioral problems clearly occur during adolescence. On the other hand, the majority of adolescents pass through this developmental period with no more than transient or mild signs of impairment stemming from psychopathology.

Four observations surface repeatedly in discussions of the development of psychopathology in adolescence (Masten, 1988). First, there is a notable increase in the prevalence of certain types of psychopathology during adolescence, including depression, social anxiety, eating disorders, psychosis, and substance abuse and dependence. Many, if not most, disorders have their initial onset during adolescence (Kessler et al., 2005). Such data support the notion that early adolescence is a period of heightened vulnerability for affective and behavioral disorders. In each case, these changes in prevalence appear relatively dramatic. For example, Major Depressive Disorder (MDD) is relatively rare before puberty. However, adolescents face a particularly high risk for MDD upon entering puberty. Even by conservative estimates, point prevalence of MDD changes during this developmental period from less than 5% to more than 10% (Angold, Costello, & Worthman, 1998; Costello et al., 2002).

Second, there are important changes in the manifestations of many forms of psychopathology during adolescence. For example, the cognitive symptoms of depression, such as hopelessness, become a more salient feature of affective disturbance as individuals become more capable of hypothetical and abstract thinking. In fact, maturation in cognitive processes early in adolescence are thought to create a new state of vulnerability in some individuals. The combination of adverse life experiences with this underly-

ing cognitive diathesis that becomes manifest during adolescence is thought to account for adolescent increases in rates of MDD (Hankin & Abramson, 2001). Similarly, the outward manifestations of conduct problems become more serious, as antisocial behavior becomes connected more with criminal activity. Notably, relatively few studies examine the way symptom profiles are transformed between childhood and adolescence and between adolescence and adulthood (but see, e.g., Avenevoli & Steinberg, 2001).

Third, new patterns of gender differences in psychopathology emerge during adolescence. Most notably, whereas rates of depression are similar among boys and girls prior to puberty, by middle adolescence depression is twice as common among females as males, a ratio that is maintained into and through adulthood. Interestingly, some evidence suggests that opposite trends emerge for behavioral disorders, with decreasing gender divergence for various markers of behavior problems (Moffitt & Caspi, 2001). The emergence or intensification of gender differences in affective psychopathology in adolescence is consistent with the more general intensification of gender differences in personality and behavior that occurs during the 2nd decade of life (J. P. Hill & Lynch, 1983). Any comprehensive theory about why psychopathology increases in adolescence must be able to account for impressive gender differences in relative rates of certain disorders.

Finally, some, but not all, forms of psychopathology in adolescence have shown important changes in prevalence over historical time, generally, with prevalence increasing with successive generations. Thus, although the process of transition from childhood to adulthood has probably always held hazards for human development, current conditions of adolescent development may have elevated the risk for specific problems that can be observed in patterns of risk-taking behaviors, affective disturbance, eating disorders, and substance abuse. We recognize that considerable complications arise in efforts to examine changes in prevalence of adolescent mental disorders over time. Given changes in perceptions of various sorts of mental illness and advances in methods for assessing rates of psychiatric disorders over time, the sensitivity for detecting disorders may change across successive cohorts of adolescence. However, data on completed suicide appear to be less susceptible to these influences than data on specific conditions such as MDD. Data documenting increased during adolescence in rates both of completed suicide and Major depression during the second half of the twentieth century suggest that rates of psychopathology among adolescents have genuinely increased (Costello et al., 2002). These historical changes

suggest that, despite the obvious importance of biological change as a defining feature of adolescence and a potential contributor to psychopathology, contextual factors must play a very important role in the development of affective and behavioral problems during this period.

ADOLESCENT DEVELOPMENT, SELF-REGULATION, AND PSYCHOPATHOLOGY

There has been a recent paradigm shift in the study of adolescent psychopathology away from seeing psychological disturbance during adolescence as either the grown-up version of childhood disorder or the immature or prodromal counterpart of adult pathology. In our view, the study of psychopathology in adolescence necessitates the study of clinical phenomena in the context of adolescence as a developmental period, rather than the study of clinical phenomena among individuals who merely happen to be older than children and younger than adults. For example, adolescence represents a time of unusual passion, manifest in extreme levels of reported feeling states. These normal developmental changes appear to be reflected in the manifestations of adolescent episodes of MDD.

A more comprehensive approach to research in this area requires linking developmental changes in the prevalence, nature, and manifestation of psychopathology in adolescence to specific aspects of biological, cognitive, emotional, social, and contextual transformation that define the period. Thus, for example, one might study the specific links between changes in depressive symptomatology and the development of abstract thinking, hormonal changes related to pubertal processes, and school transitions in early adolescence, or the connections between changes in peer relations, body shape, school contexts, and media utilization and the development of eating disturbances. Unfortunately, however, most studies of the development of psychopathology in adolescence chart symptoms of disturbance as a function of chronological age (a poor proxy for development) and do not examine how these same symptoms vary as a function of various aspects of intraindividual and contextual transformation.

We share with numerous other writers the belief that many aspects of psychopathology can be usefully cast as problems of self-regulation (see Steinberg & Avenevoli, 2000). With reference to adolescence in particular, we begin from the premise that adolescence is characterized by an increased need to regulate affect and behavior in accordance with long-term goals and consequences, often at

a distance from the adults who provided regulatory structure and guidance during childhood. In fact, this characterizes the central psychological task of adolescence in contemporary society. (Data on the development of a sense of identity, long portrayed as the fundamental developmental task of the period, e.g., Erikson, 1959, shows that most of the psychological work surrounding this issue takes place in late adolescence and early adulthood; Waterman, 1982.) As they mature toward adulthood, adolescents must increasingly control their *own* feelings and actions on the basis of learned principles, rules, and future risks and rewards that may not seem emotionally salient in the moment. This process is not simply a matter of cognitive understanding of consequences (e.g., knowing the risks of HIV, pregnancy, or driving drunk or the long-term rewards of hard work, discipline, or academic accomplishments). Rather, adolescents must develop the ability to use such knowledge to reliably guide behavior in the absence of adult supervision.

Further, this new level of self-regulation must be achieved at the same time that maturational changes may alter the nature and strength of emotions evoked by contexts that are also undergoing change. Successful navigation of *behavior* through complex social challenges and ambiguous conflicts in adolescence requires a complex balancing of many strong competing feelings related to goals, fears, and desires. Mature judgment and behavioral control in the face of strong feelings and desires are only partially in place at the end of childhood and are skills that continue to show maturational improvements well beyond early adolescent years and into the mid-20s. It is precisely this increased ability and necessity of integrating maturing cognitive elements and emerging emotional and motivational factors in a complex system of conscious control that is in many ways the hallmark of adolescence (Keating, 2004). As noted earlier, contemporary neuroscience evidence supports the view that systematic integration of an “executive suite” lies at the core of the adolescent transition (Keating, 2004), shown particularly in the enhanced development of the prefrontal cortex, in expanded corticocortical communication (prefrontal and whole brain increases in white matter density), and in apparent synaptic pruning (proliferation and then decrease in gray matter density).

Puberty and adrenarche (the maturation of the adrenal system that occurs in preadolescence), however, begin to exert large changes in young bodies and brain systems more than a decade before mature judgment and self-control are achieved. The temporal gap between the heightened arousal set in motion by puberty and the onset of adult like

regulatory competence, which does not fully mature until early adulthood, creates the special vulnerability and challenge of adolescence. One explanation for the historical rise in the prevalence of many forms of psychopathology is that this gap has become more pronounced over the course of the past century, especially among girls. Specifically, there has been a dramatic historical change toward the earlier onset of puberty among girls such that menarche (one of the *final* events in female pubertal maturation) typically occurs *before* age 13 in most industrialized societies. Further, the early rise in adrenarcheal hormones (an early maturational process associated with puberty) is well under way by 8 to 9 years of age in both boys and girls. (We do not have historical data on whether adrenarche occurs earlier today than in previous eras, but there is reason to suspect that this is the case given the secular trend in menarche and other external manifestations of puberty.) The onset of puberty in children not only impacts physical growth and sexual maturation, but also activates new drives, impulses, emotions, motivations, changes in arousal, and new behaviors and experiences that challenge self-regulatory abilities. Therefore, early adolescence in contemporary society is a time of potential mismatch between rapidly changing emotional and motivational systems and the slowly maturing systems of self-control.

These interrelated emotional, motivational, physical, and cognitive developments must also be considered in light of the context of early adolescence in modern life. Three aspects of the context of contemporary adolescence are especially important. First, the dramatic historical change to earlier onset of puberty impacts not only the physical aspects of development but also the social experiences of young adolescents. The appearance of secondary sex characteristics at an earlier age likely leads to the earlier onset of dating, romantic involvement, and sexual experimentation. In addition, in light of research suggesting that changes in the physical appearance of individuals at puberty provoke changes in parent-child relations, especially with respect to increases in adolescent assertiveness and autonomy seeking (e.g., Steinberg, 1988), the earlier onset of puberty may set in motion changes in family dynamics before parents expect these shifts to occur. As Collins (1990) has noted, difficulties in parent-child relationships often increase when family members' expectations of each other are "violated." Previous generations of parents may have expected, and perhaps tolerated, increased autonomy seeking in their child when it occurred in conjunction with the adolescent's entrance into the labor force, for example, but today's parents may react very dif-

ferently to the same sort of assertiveness now that it comes at a much earlier age.

Second, young adolescents are typically dealing with increasingly more difficult decision making and challenges to self-control in complex environments that activate many arousing but conflicting feelings and desires, as well as the need to navigate complex choices and ambiguities. The range of options available to adolescents, from choosing among alternative sources of entertainment to choosing among alternative educational or vocational pathways, has increased dramatically in contemporary industrialized society. Thus, today's adolescents face more decisions, and more complicated decisions, than their counterparts did in previous eras. These changes are reflected in higher rates of adverse experiences that are thought to interact with maturation in cognitive capacities to precipitate episodes of depression in vulnerable individuals.

Third, there has been a historical shift toward increased behavioral autonomy among teenagers, such that external constraints on their behavior (in the form of parental and adult supervision) are diminishing and are often absent. Changes in patterns of parental employment, in rates of divorce and separation, and in patterns of residential mobility, which have led to disruptions in community ties, have decreased the amount of time that young people spend in the company of parents, adult neighbors, and members of their extended family. As a consequence, today's adolescents have fewer resources on which to draw in the task of regulating new emotions and drives. These contextual changes may exacerbate special vulnerability of adolescents to emotional and behavioral problems.

In this chapter, we argue that disjunctions in biology, cognitive capability, and contextual demands in adolescence create vulnerabilities for certain types of emotional and behavioral difficulties, in particular, those that involve the regulation of affect (e.g., depression, social anxiety), appetite (e.g., substance abuse and dependence, eating disorders), and impulsivity (e.g., antisocial behavior, excessive risk taking). The framework we propose is relevant to the study of a wide range of psychopathologies, including internalizing, externalizing, and addictive disorders. To understand the development of psychopathology in adolescence, therefore, we need to understand changes in patterns of arousal and motivation, the development of regulatory competence, and the ways this competence may be compromised or strengthened by the interplay among biology, cognition, and context.

In each of these areas of study, there have been major scientific advances in recent years. A conceptual framework to

productively advance our understanding must therefore confront two competing demands. The first is to capture the complexities of development within and between multiple domains. The second is to draw a picture of the interplay among multiple systems that is sufficiently coherent to organize a research agenda and to inform policy and practice.

Three propositions guide the framework we offer in this chapter. First, we hypothesize that various forms of psychopathology in adolescence are related to the neurobehavioral changes of puberty, which include changes in brain systems regulating arousal and appetite that subsequently influence the intensity and duration of emotion and motivation. Adolescents, we hypothesize, experience emotions and motivations that are qualitatively and subjectively stronger than those experienced by prepubertal children. Thus, for example, whereas children experience sadness, euphoria, anxiety, and anger, the biological changes of puberty result in the capacity of individuals to feel sadder, more euphoric, more anxious, and angrier and, furthermore, to experience these more intense affective states for longer periods of time. Similarly, the biological changes of puberty stimulate changes in the intensity and duration of various drives, not only the sex drive, which is presumed to intensify at puberty, but all drives relevant to reward, novelty, and stimulation seeking. In addition, motivational drives related to social status appear to increase during adolescence.

Second, we hypothesize that the increased intensity and duration of emotion and the increased strength of at least some appetitive drives create new regulatory challenges, particularly with respect to self-regulation in the face of high-intensity emotions and motivation and in the midst of emotional conflicts. During adolescence, there is a shift in regulatory capability away from regulation that is assisted by external agents, such as parents, toward regulation that is primarily internal, cognitive in nature, and involving higher-order executive functioning. The type of executive function that is assembled during the adolescent transition is in fact an integration of a number of specific cognitive achievements, particularly in planning, monitoring, evaluating, and reflecting. Together, these can be thought of as an executive suite that comes increasingly, but gradually, under conscious control during adolescence (Keating, 2004). Because the maturation of regulatory systems relevant to the modulation of emotion and motivation is not driven by pubertal development and is still taking place during late adolescence, however, adolescents are relatively more vulnerable than children (whose levels of arousal and motivation are lower) or adults (whose regula-

tory capabilities are stronger) to extremes in affective and drive states, which may leave adolescents more susceptible to psychopathology. Regulatory problems may result either from inadequate or incompletely developed regulatory capacities or both. Bringing the potent and novel affective and motivational systems into an integrated, functioning system is a lengthy and effortful process. Thus, emotional and behavioral disorders may result from underregulation (e.g., where the underregulation of anger may lead to conduct problems) or inappropriate regulation (e.g., where the overregulation of sadness by rumination may lead to the development of depressive disorder). As regulatory capacities mature, individuals become less susceptible to the development of psychopathology.

Third, we hypothesize that during the period of greatest disjunction between affect and appetitive motivations on the one hand, and regulatory competence on the other, individuals may be protected from extremes in emotion or drive by a context that provides adequate external regulation in the form of support, control, and predictability. Thus, although many individuals may experience emotions and drives whose intensity and duration exceeds their regulatory competence, those adolescents who enjoy supportive home, peer, school, and neighborhood contexts are buffered from the ill effects of the emotion-cognition disjunction. In addition, their transition to an internal, consciously controlled regulatory system is more effectively scaffolded compared with individuals lacking in such support. Conversely, individuals whose environments do not provide sufficient support, control, and predictability are relatively more vulnerable to the development of psychopathology. In our view, the adolescent is not merely the passive recipient of contextual support, however. We view context as a resource that is both provided by outside agents (such as parents or teachers) and also actively recruited by adolescents. An important, yet remarkably understudied question, is how individuals develop the capacity to identify, enlist, and employ sources of contextual support during times of stress as a means of protection against the development of emotional and behavioral difficulty. In this regard, *resilience* in the face of adversity may reflect in part the ability to engage contextual resources in the service of self-protection.

BRAIN DEVELOPMENT IN ADOLESCENCE

Despite the widely held notion that the brain “changes” at puberty, there is a surprising dearth of neuroscience data

that specifically refer to the links between brain development and pubertal maturation. As a consequence, in this section, we draw on other areas of neuroscience that frame our understanding of maturational changes more specific to the interval surrounding pubertal development. This includes general aspects of brain development, contextual effects on brain development, and a discussion of what is known about changes in brain function in specific brain regions during adolescence.

It is important to note at the outset that not all brain development in adolescence is closely linked to processes of pubertal maturation. One limitation of extant views of adolescent development, and of psychopathology in adolescence in particular, is that “biology” has been used as an explanatory construct without sufficient attention paid to the fact that biological change in adolescence is multi-systemic, and that even pubertal change itself is not a unitary phenomenon. Thus, it is important to distinguish between aspects of brain development and function that are closely tied to puberty and those that appear to take place relatively independent of pubertal maturation (i.e., that follow a different timetable and are influenced by other aspects of aging and/or experience). Moreover, even within puberty, some aspects of brain development may be particularly heavily influenced by specific facets of puberty but unrelated to others (e.g., those that are closely linked to changes along the hypothalamic-pituitary-adrenal axis versus those that are closely linked to changes along the hypothalamic-pituitary-gonadal axis).

Research on the impact of biology on psychopathology in adolescence is further complicated by the fact that some links between biology and behavior are best understood with reference to neurobiological processes unfolding in brain systems, others with respect to endocrinological processes occurring at a more holistic level, and still others with regard to changes in the physical appearance and competencies of the adolescent. Thus, to say that the onset, intensification, or transformation of any form of psychopathology in adolescence is linked to the biological changes of the period is no longer adequate, given our understanding of the complexity of biological change during the years between childhood and adulthood. As we move forward into the twenty-first century, questions about biological change and psychological functioning in adolescence will need to be framed with much greater specificity. Some aspects of functioning are linked to puberty, others are linked to biological change that takes place in adolescence but that is not pubertal in nature, and still others are linked only secondarily to

processes of normative biological maturation. And among those changes linked to puberty, there is considerable heterogeneity with respect to the aspects of pubertal maturation that are most important.

Brain Development in Mammalian Species

Brain development in mammalian species follows an orderly progression that begins with differentiation of the brain and spinal cord in the longitudinal, circumferential, and radial dimensions. This process is followed by increases in cell numbers, repositioning of cell locations, and maturation of connections among brain cells and supporting constituents (Nowakowski & Hayes, 1999; Rakic & Nowakowski, 1981). Three aspects of brain development appear relevant for theories of developmental psychopathology in adolescence. First, perhaps the most extensive data relate to evidence of active changes within cells after they have already ceased to divide (Kolb, Forgie, Gibb, Gorny, & Bowntree, 1998; Lewis, 1997). There is robust evidence of prolonged refinements in synapses, the connections among nerve cells, well into adolescence, as reflected by changes in the morphology and functional integrity of dendrites, the part of the neuron or nerve cell that receives information from other parts of the nervous system. Synapses exhibit marked changes during adolescence in absolute number, precise localization on dendrites, and functional integrity (Kolb, 1999). In general, there is some evidence that such changes occur more profoundly in parts of the brain devoted to multimodal sensory processes or abstract motor plans, as opposed to primary sensory areas involved in perception of low-level stimulus features or primary motor areas involved in control of isolated muscle groups. On the other hand, only broad, tentative conclusions can be made about the nature of these changes in adolescence, given the relatively limited developmental research on region-specific patterns of cellular differentiation in humans or among nonhuman primates (Fuster, 1997; Huttenlocher, 2002; Lewis, 1997). Developmental changes of ascending brain stem monoamine systems effects on cortical-cortical synapses may be particularly important as regulators of behavior. For example, studies in nonhuman primates demonstrate adolescent maturation in dopaminergic innervation of neurons in the prefrontal cortex (Goldman-Rakic, 1987; Kolb, 1999; Lewis, 1997). Advances in neuroimaging methodology provide the means for generating comparable data in human adolescents (Gogtay et al., 2004; McClure et al., 2004; Monk et al., 2003; Thompson, Cannon, & Toga, 2002).

Second, conduction along neurons is facilitated by the maturation of myelin sheaths. There is evidence of extensive myelination during adolescence, though this evidence carries less direct implications for current theories of normative and psychopathological functioning, given the incomplete understanding of relations between myelination and cognitive function (Evans et al., 1999; Fuster et al., 1997; Gabrielli et al., 1999; Kolb, 1999). On the other hand, to the extent that cortical-cortical interactions represent a key aspect of complex thought, maturation in myelination, by increasing the speed of nerve cell conduction, is likely to facilitate maturation in complex thought processes.

Finally, recent studies provide emerging evidence that new neurons may actually arise in at least some brain regions, particularly the hippocampus and olfactory cortex (Gould & Tanapat, 1999). This represents a relatively marked departure from initial thinking on aspects of primate neural development, which did not allow for the genesis of new neurons after early development. In the hippocampus, where adult neurogenesis has been most convincingly documented, newly synthesized neurons are integrated into extant neural circuits to refine acquired abilities (Gould & Tanapat, 1999). Taken together, data on synaptic plasticity, myelination, and neurogenesis suggest that refinements in neural connectivity represent key neural processes that are relevant for understanding normative and atypical adolescent development.

An emerging irony in the expanding horizon of neuroscience research relates to the growing shortage of developmentally oriented studies necessary for informing integrative perspectives on human adolescence. Whereas working knowledge of brain circuitry is growing in an exponential fashion, knowledge is growing relatively slowly in areas related to developmental or pubertal influences on brain circuitry. Work in developmental psychology, clinical neuroscience, and psychiatry raises key questions pertaining to changes in brain function during puberty related to the regulation of affective states. These questions reflect the fact that puberty signals relatively abrupt changes in behavior, particularly emotionally modulated behaviors, in humans and other mammals. Neuroscience research encounters considerable hurdles in attempting to address developmental questions related to emotion and pubertal development among humans, however. Much of the neuroscience database derives from studies of rodents (LeDoux, 1998). Such work carries unclear implications for humans, however, given the large cortical contribution to the regulation of emotion in primates (Rolls, 1999). Conversely, much of the clinical database derives from observations of symptom patterns, which are not easily

modeled in animals. In the current chapter, emphasis is placed on clinical data from neuropsychology, electrophysiology, and brain imaging methods. These methods generate data in humans that can be more readily compared to data in nonhuman primates and rodents. Finally, independent of any changes related to puberty, other aspects of brain development are likely to impact adolescent changes in behavior over relatively prolonged periods. Here, too, considerable research is needed that delineates changes across the full adolescent period as they impact aspects of abstract thinking and other cognitive abilities that continue to emerge long after pubertal transitions have ceased.

Contextual Effects on Brain Development

Discussions of brain development in adolescence and its implications for psychopathology must acknowledge not only the importance of normative maturational processes during this time but also the role of the environment in shaping patterns of growth and maturation. Brain development appears to be more plastic and susceptible to environmental influence in adolescence than had been previously thought. Indeed, current neuroscience research on contextual influences suggests that environmental factors might conceivably profoundly affect brain development in adolescence and that neurodevelopmental processes are affected on varying time scales. Thus, one of the reasons for the heightened vulnerability of adolescents to various forms of psychopathology could inhere in the vulnerability of the adolescent brain to contextual influence. To most clearly summarize available data, this section separately discusses long-term, intermediate, and acute effects of context on brain function, while acknowledging the somewhat artificial nature of these temporal distinctions.

In terms of effects that persist across the life span, some contextual factors produce permanent change in neural circuitry by affecting developmental processes. One of the best-understood effects in this area derives from the work by Meaney and colleagues (Liu et al., 1997; Meaney, 2001b), revealing an effect of handling manipulations on rodent pups prior to adolescence. Contextual manipulations early in development permanently alter the rat's physiological response to various stressors by affecting the sensitivity of feedback regulation in limbic brain regions, including the hippocampus and ventral prefrontal region. The precise developmental period during which these effects can occur has not been established. Interestingly, however, it appears that an enriched social and learning environment during the peripubertal period in rats is capable of reversing many of

the adverse effects of early maternal separation (Francis, Diorio, Plotsky, & Meaney, 2002) and that these experiences later in development influence some, but not all, of the brain systems impacted by the early handling and separation paradigms. Variations in maternal care alter the expression of genes that regulate responses to stress, synaptic development in the hippocampus, and later maternal behavior among female offspring (Meaney, 2001a).

Other work, examining contextual effects on synaptic plasticity in the rodent cerebral cortex, emphasizes the need for research on contextual effects on prefrontal and limbic regions in adolescence. In work on plasticity in the cortex, contextual manipulations exert effects on dendrite patterns in adult animals, and these effects vary as a function of developmental stage (Greenough, Black, & Wallace, 1987; Kolb, 1999). Contextual factors appear to produce, particularly robust long-term changes in dendrites when they operate during periods of intense synapse formation. This is important, because some regions of the brain may undergo particularly marked synapse formation in adolescence (Lewis, 1997), and as a result, the development of these brain regions may be particularly susceptible to the effects of context. This emphasizes the need to extend work exemplified in the studies from Meaney and colleagues through the adolescent period.

Beyond such long-term neurodevelopmental effects, other studies demonstrate contextual effects on neural function that operate over days to weeks. Such intermediate effects are elucidated in a particularly compelling fashion through studies examining the response, following contextual manipulations, in the hippocampus, a part of the brain in the temporal lobe involved in memory. Specifically, relatively brief periods of stress alter dendrite patterns in one group of neurons as well as survival rates for another group of newly generated neurons. Interestingly, less extreme contextual manipulations, such as learning experiences, can exert comparable effects. Both monoamines and neurohormones are central regulators of these processes. As a result, changes in the functioning of monoamine and neurohormonal systems during puberty may alter the response of neural systems, including the hippocampus, to contextual effects operating on an intermediate time scale.

Finally, contextual factors exert acute effects on functioning in neural circuits. Because these effects are at least partially mediated by systems that undergo robust developmental changes during adolescence, acute contextual effects on neural function may change with the initiation of puberty. For example, hormonal systems that signal the onset of puberty have robust effects on functional aspects of neural sys-

tems in animals that appear relevant for human cognitive functioning. A series of neuroimaging studies among adults demonstrates a robust effect of sex hormones on executive tasks that engage prefrontal regions (Berman et al., 1997; Shaywitz et al., 1999). Given the particularly high levels of steroid hormone receptors in medial temporal regions, changes in the hormonal milieu during adolescence may also affect performance on tasks that engage these regions. Similarly, autonomic systems that mature during puberty affect functional aspects of neural systems in animals. For example, emotional modulation of mnemonic functions results from the acute peripherally mediated effects of stress on the noradrenergic system that, in turn, affects a neural circuit involving the basolateral amygdala and hippocampus (Roosendaal, 2002). Sensitivity of the noradrenergic system to stress, as reflected in peripheral measures, appears to increase during the pubertal years (Galanter, Wasserman, Sloan, & Pine, 1999). Finally, contextual factors may exert unique acute effects on brain function during adolescence due to interactions between changes in hormonal or autonomic systems and the underlying brain regions on which they act. For example, executive functions mediated by dorsal prefrontal regions are modulated by dopamine input to this region (Arnsten, 1999). Stress effects on prefrontal function may change during adolescence due to developmental changes in the dopamine system as well as in prefrontal targets (Lewis, 1997). These changes may be particularly observable during adolescence, in light of the key modulatory role for the dopamine system in prefrontal functions (Cohen, Aston-Jones, & Gilzenrat, 2004). Hence, changes in the hormonal, autonomic, and monoamine milieus during adolescence may alter the brain's response to acute stress.

Adolescent Development in Specific Brain Regions

As elucidated in the preceding section, adolescence may represent a time of marked cellular differentiation in brain regions known to play a role in emotional regulation. The nature of ongoing neural processes in these regions at adolescence may create a window for particularly marked effects of context on emotional processing (Kolb, 1999). This section summarizes available data on adolescent brain development that support this possibility. Because data for the prefrontal and the inferior temporoparietal cortices most clearly support this premise, only data for these specific brain regions are reviewed. Nevertheless, given changes during adolescence in monoamine and hormonal systems with widespread modulatory influences, changes during this period in other brain regions may exert equally compelling effects on behavior.

Changes in the prefrontal cortex represent one of the most consistently studied aspects of adolescent brain development. Data from neuropsychology, brain imaging, and postmortem studies in primates all point to considerable changes in prefrontal structure and function in adolescence. Given the complexity of this brain region and the wealth of available data, considerable disagreement remains on the most appropriate model of prefrontal function. Nevertheless, most investigators view one set of functions as particularly dependent on dorsal aspects of this brain region. These include functions usually subsumed under the concepts of “working memory” and “preparatory set.” Another set of functions is typically viewed as particularly dependent on ventral or orbitofrontal aspects of the prefrontal cortex. These include functions often subsumed under the concept of “inhibitory functions.” Ventral frontal regions in particular also may be more intimately tied to the calibration and regulation of emotions or behaviors associated with rewards and punishments. Finally, a third set of functions related to motivation and performance monitoring typically is viewed as dependent on medial frontal regions, including the cingulate gyrus.

There is some evidence that dorsal aspects of the prefrontal cortex reach functional maturity later in adolescence, as compared to ventral and medial aspects of the prefrontal cortex. This evidence derives from neuropsychological studies in humans (Luciana & Nelson, 1998), brain imaging studies in humans (Chugani, 1999; Giedd et al., 1999; Thompson et al., 2000), and postmortem studies in nonhuman primates (Lewis, 1997). Interestingly, this may require that certain functions ordinarily subserved by the dorsal region in adulthood be mediated by ventral regions prior to late adolescence. For example, at adolescence, transient deactivation of dorsal prefrontal regions has an increasingly profound effect on certain functions, such as delayed response, usually attributed to this region (Alexander, 1982). As such, these developmental data raise the possibility of an asynchrony between developments in prefrontal regions most intimately tied to emotion (which appear to come online relatively earlier in adolescence) as opposed to those most closely linked to executive functions (which appear to come online relatively later). Surprisingly little is known about the functional development of the ventral, medial, and orbitofrontal regions of the cortex, however, or about the interrelations between functions that are mediated in the ventral and dorsal regions—and this represents a critical area of focus for current and future research aimed at understanding the development of affect regulation and the emergence of self-regulatory capacities in adolescence (as discussed in more detail in the following section on affect regulation).

Changes in the temporoparietal cortex represent a second aspect of brain development where there is evidence of adolescent changes. This brain region plays a key role in forming representations of objects through the integration of more specific perceptual aspects of objects. In terms of emotional salience, studies in nonhuman primates document interactions between inferior temporal regions and medial temporal structures, including the amygdala and hippocampus. As reviewed elsewhere (Pine, 2003), maturation in linguistic capacity may signal maturation of the ventral temporal region. This maturation may reflect a stronger role for linguistic and other cognitive processes related to categorization skill in the regulation of emotion.

In summary, then, although research on adolescent brain development is still in its infancy, there is considerable evidence that the 2nd decade of life is a period of great activity with respect to changes in brain structure and function, especially in regions and systems associated with response inhibition, the calibration of risk and reward, and emotion regulation (see Dahl & Spear, 2004). Contrary to earlier beliefs about brain maturation in adolescence, this activity is not limited to the early adolescent period, or is it invariably linked to processes of pubertal maturation. Two particular observations about brain development in adolescence are especially pertinent to our understanding of the development of psychopathology during this period. First, the fact that much brain development during adolescence is in the particular brain regions and systems that are key to the regulation of behavior and emotion and to the perception and evaluation of risk and reward is important, as many forms of psychological disorder in adolescence are linked conceptually and empirically to problems in impulse control, sensation seeking, and affect regulation. Second, growing evidence that patterns of brain change in adolescence are susceptible to environmental influence suggests that contextual factors undoubtedly play an important role in accounting for individual differences in patterns of normative and atypical development. The integration of neuroscience-based research efforts with those that are more contextually oriented will permit a vast improvement in our understanding of how context gets “into” the brain during the adolescent years and how this process may help inform future study of the onset and developmental course of psychopathology.

AROUSAL, MOTIVATION, AND AFFECT REGULATION DURING PUBERTY AND ADOLESCENCE

As noted earlier, the framework we have proposed emphasizes the links between psychopathology and self-regulation

in adolescence. Central to our argument is the notion that changes in arousal and motivation brought on by pubertal maturation precede the development of regulatory competence in a manner that creates a disjunction between the adolescent's affective experience and his or her ability to regulate arousal, motivation, and emotion, all of which have implications for the regulation of behavior. As we have noted elsewhere (e.g., Dahl, 2001), the developments of early adolescence create a situation in which one is starting an engine without yet having a skilled driver.

In this section, we outline some of the emerging understanding regarding maturational changes in arousal, motivation, and emotion during adolescence. This includes some discussion of the neurobiology of affect regulation and the regulation of sleep and arousal. Affect regulation is considered within a framework of the developing neurobehavioral systems that underpin emotion and its regulation, systems that are hypothesized to be of clinical relevance to understanding affect dysregulation and the emergence of affective and behavioral disorders in adolescence.

The Neurobiology of Affect Regulation

From a neuroscience perspective, emotions have been conceptualized as brain states associated with rewards and punishments (Rolls, 1999). Affect regulation involves major contributions from a group of interconnected brain structures, including the amygdala, extended amygdala/ventral striatum, and several cortical areas, particularly areas of the medial and orbitofrontal cortex (Davidson, 2000; Davidson, Jackson, & Kalin, 2000; Davidson, Pizzagalli, Nitschke, & Putnam, 2002; Drevets, 2003; Rolls, 1999). Medial frontal areas, encompassing the anterior and posterior cingulate cortex, appear to be involved, especially in situations of performance monitoring, response conflict, and/or error detection in relation to an emotional state (Carter et al., 1998). The amygdala is typically recognized as a key structure for integrating the perception of rewarding/punishing stimuli and orchestrating some aspects of an organism's response to these stimuli. In terms of acute regulation of these responses, neurons in some amygdala nuclei exhibit long-term potentiation as well as habituation following the pairing of a rewarding or punishing stimulus with a neutral stimulus (Rogan, Staubli, & LeDoux, 1997). Neurons in other amygdala nuclei may undergo sensitization under different stimulus-pairing conditions (Davis, 1992). The degree to which intrinsic aspects of amygdala functions change during adolescence remains unclear. The underlying circuitry of the primate amygdala, as well as its connections with key afferents and efferents, appears to develop relatively early in life.

Nevertheless, Kellogg and colleagues (Kellogg, Awatramani, & Piekut, 1998) have documented increases during adolescence in stress-induced gene expression in the rodent amygdala. Such adolescent changes could partially reflect changes in other structures or hormonal systems that interact with amygdala nuclei as part of circuits mediating responses to reward and punishment.

Left unclear in extant attempts to apply affective neuroscience methods to the investigation of affective disorders in adolescence is specificity regarding the particular components of affect that are dysregulated. Even a cursory analysis of the complexity of most forms of psychopathology indicates how complex a problem this is. For example, the development of Major depression in adolescents could be associated with altered perception of emotional cues, a lower threshold to activate negative emotions such as sadness, a tendency to activate a greater intensity of negative affective states, difficulties terminating negative affective states once they are activated, difficulties activating *positive* emotional states, altered interpretation or monitoring of internal affective states, or patterns of behavior resulting in fewer emotionally rewarding experiences—or, most likely, some combination of these and other factors. Similarly, the development of conduct problems could be due to deficient capacity in using emotion or emotion-related attentional processes in the regulation of behavior, difficulties in the regulation of appetitive drives, problems in the regulation of affective states such as anger, deficiencies in inhibitory control, or some amalgamation of these.

Pubertal Maturation and Affective Development

In contrast to most measures of cognitive development, which seem to correlate more closely with age and experience rather than the timing of pubertal maturation, there is evidence for a specific link between pubertal maturation and developmental changes in various aspects of arousal, motivation, and emotion. For example, there is evidence that pubertal development directly influences the development of romantic interest and sexual motivation (Udry, 1987). There is also evidence that some changes in emotional intensity and reactivity are more closely linked to pubertal maturation than to age, such as measures of parent-adolescent conflict (Steinberg, 1987). Some cognitive skills related to human face-processing have also shown intriguing alterations in midadolescent development: an apparent *decrement* in face-processing skills that is associated with sexual maturation (measured by Tanner staging by physical examinations) rather than with age or grade level (Diamond, Carey, & Back, 1983). A parallel finding

has been reported for voice recognition (Mann, Diamond, & Carey, 1979).

There is also evidence that the increase in sensation seeking and risk taking and some proclivity toward reckless behavior is influenced by puberty. For example, in a recent study by Martin et al. (2002), where sensation-seeking and risk-taking behaviors were examined in a large group of young adolescents ages 11 to 14, there was no significant correlation between age and sensation seeking, but a significant correlation between sensation seeking and pubertal stage among both boys and girls. There is also evidence in animal and human studies supporting a link between increasing levels of reproductive hormones and sensitivity to social status (Book, Starzyk, & Qunisey, 2001; Josephs, Newman, Brown, & Beer, 2003), which is consistent with the link between puberty and risk taking, as several influential theories of adolescent risk taking (e.g., Moffitt, 1993) suggest that at least some of this behavior is done in the service of enhancing one's standing with peers. There is evidence, as well, that adolescent girls prefer and find more attractive dominant and aggressive boys, although this preference appears to wane as girls mature out of adolescence (Pellegrini & Long, 2003).

Sleep and Arousal at Puberty

Another area of investigation where puberty-specific maturational processes have been well documented concerns changes in the regulation of sleep and arousal. Dahl, Trubnick, al-Shabbout, and Ryan's (1997) longitudinal study of normal sleep found that changes in REM sleep measures showed a strong link to pubertal increases in reproductive hormones, whereas changes in stages 3 and 4 non-REM sleep appeared to be more strongly linked to the rapid physical growth at puberty (as measured by body mass index). There is also a circadian shift (delay) resulting in a biologically based tendency to stay up later (and sleep in later) that occurs in early to midpuberty and an increase in objectively measured daytime sleepiness (which may represent an increased biologic need for sleep during pubertal maturation; Carskadon, 1990, 1999; Carskadon et al., 1980). There are also maturational changes in the effects of sleep loss in adolescence. By midpuberty, adolescents show much greater objectively measured sleepiness, as well as complex changes in mood and affect regulation, in response to sleep loss (Dahl, 1996, 1999; Dahl, Bernhisel-Broadbent, Scanlon-Holdford, Sampson, & Lupo, 1995; Dahl, Pelham, & Wierson, M., 1991; Maayan et al., 1998).

The impact of pubertal change on sleep and arousal may have important implications for the development of psycho-

pathology. In addition to the direct effects of sleep loss on mood and motivation, sleep loss in adolescents can also increase stimulant use during the day (including caffeine, nicotine, and methylphenidate, as well as illicit stimulants). Some of the behavioral adaptations to accumulated sleep loss (such as extensive catch-up sleep on the weekends by sleeping in very late) can also have negative effects on the slowly adapting circadian systems. In these ways, it appears that insufficient sleep can sometimes contribute to a spiral of problems with emotional dysregulation. Further, adolescent depression is associated with disturbed sleep, particularly difficulties falling asleep.

Puberty and Psychopathology

Although the specific mechanisms connecting pubertal maturation and many types of psychopathology in adolescence have yet to be established, increases in certain types of affective disturbance have been convincingly linked to pubertal maturation, especially among girls. As noted earlier, the prevalence of Major depression exhibits a two- to fivefold increase during adolescence, particularly among adolescent girls, and this increase is associated with pubertal stage (Angold et al., 1998). Similarly, panic attacks are extremely rare prior to puberty but exhibit a marked increase, particularly among girls, with pubertal onset (Hayward et al., 1992; Pine et al., 1998). Angold et al. (1998) reported data from a longitudinal epidemiological sample indicating that the *rise* in pubertal hormones was the best predictor of increased risk for depression among girls.

Numerous studies have shown that individuals who go through puberty earlier than their same-age peers are especially vulnerable to a wide range of affective and behavioral disorders. Indeed, one of the most robust findings in the literature on pubertal development and adolescent adjustment is that early maturing females and, to a lesser extent, early maturing males evince relatively higher rates of virtually all sorts of adjustment difficulties, including depression and suicide, delinquency, risk taking, emotional disorders, and other psychological difficulties (Alsaker & Olweus, 1993; Caspi, Lynam, Moffitt, & Silva, 1993; Ge, Conger, & Elder, 1996; Graber, Lewinsohn, Seeley, & Brooks-Gunn, 1997; Orr & Ingersoll, 1995). As with the case of pubertal status and psychopathology, the underlying links between pubertal timing and psychopathology have remained largely unexplained. Some investigators have emphasized the effects of off-time development (i.e., different from peers) as the key factor in risk for depression (Graber et al., 1997); others have attributed the

increased vulnerability of early maturers to a wider array of problems to social factors (e.g., among girls, heightened expectations for involvement in sexual activity, especially with older boys, and among both males and females, association with older peers who may lead them into early experimentation with drugs and delinquency; Magnusson, Stattin, & Allen, 1986). Another strong possibility, suggested by our earlier analysis, is that the disjunction between changes in affective arousal (which are linked to puberty) and the development of self-regulatory competence (which is not) is wider among early maturers than their peers.

It is important to emphasize the limitations of these studies of puberty and psychopathology: Many have relied on self-report measures of pubertal development, and few have obtained objective measures of pubertal maturation or hormone levels. As a consequence, information on underlying mechanisms is sparse. Current theories adopt an integrative perspective (Angold et al., 1998; Dahl, 2001) consistent with the idea that biological changes associated with puberty increase adolescents' vulnerability to social stress, but these models are not inconsistent with those that focus more on the direct links between pubertal maturation and the development of various brain systems. Given the magnitude, significance, and complexity of these problems, there is a need for studies examining changes in affect regulation within a framework of affective neuroscience. In addition to methodological advances, there is also a need for conceptual and modeling work focused on pubertal effects on brain maturation, emotion, and emotion regulation.

In some models of the development of affect regulation, there is an explicit emphasis on cognitive systems exerting control over emotions and emotion-related behavior (see Thompson, 1994). Many aspects of affect regulation involve the ability to inhibit, delay, or modify an emotion or its expression in accordance with some rules, goals, or strategies or to avoid learned negative consequences. However, there is increasing understanding that cognitive-emotional interactions also unfold in the other direction in important ways. Thus, just as cognition has an important impact on emotion, emotion has an important impact on basic cognitive processes, including decision making and behavioral choice. These issues are not traditionally considered within the scope of affect regulation, but they are important within the larger framework of affective changes during adolescence, especially with respect to the study of psychopathology. Similarly, maturation in other aspects of cognition is thought to contribute to vulnerability for affective disturbances. For example, as individuals enter

early adolescence, they demonstrate the capacity to manifest specific cognitive profiles associated with risk for affective disturbances (Hankin & Abramson, 2001). When confronted with certain types of adverse contextual circumstances, adolescents who have developed to manifest this cognitive profile face a particularly high risk for affective disorders, particularly major depression.

Behavioral data have often made it appear that adolescents are poor decision makers (i.e., high rates of participation in dangerous activities, automobile accidents, drug use, and unprotected sex). This led initially to hypotheses that adolescents had poor cognitive skills in decision making or that information about consequences of risky behavior may have been unclear (Botvin, 1991; Tobler, 1986). In contrast to those hypotheses, however, there is substantial evidence that adolescents engage in dangerous activities *despite* understanding (cognitively) the risks involved (Benthin et al., 1995; Cauffman & Steinberg, 1995; Dahl, 2001; Slovic, 1987, 1998, 2000a, 2000b). In real-life situations, adolescents do not simply rationally weigh (in conscious thought) the relative risks and consequences of their behavior: Their actions are largely influenced by feelings (Steinberg, 2003). Likes and dislikes, as well as emotional expectancies (including fears and desires), impact strongly on behavioral choices.

In contrast to much previous work on adolescent decision making that emphasized cognitive processes and mainly ignored affective ones, there is now increasing recognition of the importance of emotion in decision making (Loewenstein & Lerner, in press). The decision to engage in a specific behavior with long-term health consequences—such as smoking a cigarette, drinking alcohol, or engaging in unprotected sex—cannot be completely understood within the framework of cold cognitive processes. (*Cold* cognition refers to thinking processes under conditions of low emotion and/or arousal; *hot* cognition refers to thinking under conditions of strong feelings or high arousal and therefore may be much more important to understanding risky choices in real-life situations.) These affective influences are relevant in many day-to-day decisions that are made at the level of gut feelings regarding what to do in a particular situation (rather than deliberate thoughts about outcome probabilities or risk value). These gut feelings appear to be the products of affective systems in the brain that are performing computations that are largely outside conscious awareness (except for the feelings they evoke; Bechara, Damasio, & Damasio, 2000; Bechara, Damasio, Damasio, & Lee, 1999). How these feelings develop and become calibrated during maturation and how the strengths of fears versus

desires are influenced by particular types of experiences at particular points in development are only beginning to be studied within the framework of affective neuroscience (Dahl, 2001). It does appear, however, that puberty and sexual maturation have important influences on at least some aspects of behavior through new drives, motivations, and intensity of feelings, as well as new experiences that evoke strong feelings (such as developing romantic involvement; Keating & Sasse, 1996; Keating & Shapka, 1999; Richards, Crowe, Larson, & Swarr, 1998). In the next section, we examine the development of the cognitive tools that permit the adolescent to regulate emotion and behavior in the face of these new and intense emotions.

THE DEVELOPMENT OF REGULATORY COMPETENCE IN ADOLESCENCE

A central feature of the emerging framework on adolescent psychopathology we propose is the role of regulatory systems. During the adolescent transition, we argue, regulatory systems are gradually brought under the control of central executive functions, with a special focus on the interface of cognition and emotion. In this section, we provide a new look at cognitive development in adolescence that is grounded in recent discoveries in neuroscience and examine the significance of cognitive change in adolescence for the development of regulatory competence.

Two important observations about cognitive development in adolescence are especially relevant to our assertion that psychopathology in adolescence is related to the disjunction between affective arousal and regulatory competence. The first is that the development of an integrated and consciously controlled executive suite of regulatory capacities is a lengthy process. Yet, adolescents confront major, emotionally laden life dilemmas from a relatively early age—perhaps, as we have suggested, getting earlier over historic time, with a decline in the age of pubertal onset and in the age at which a wide range of choices are thrust on them.

The second observation is that the acquisition of a fully coordinated and controlled set of executive functions occurs relatively later in development, both ontogenetically and phylogenetically (Keating, 2004). As such, it is less likely to be canalized (to the same degree as, say, early language acquisition), leaving greater opportunities for suboptimal trajectories. As noted, these suboptimal patterns of development take many different forms, clusters of which are associated with broad categories of psychopathology,

such as the excessive down-regulation of mood and motivation that characterizes many internalizing difficulties or the inadequate control of arousal that is associated with a wide range of risky behaviors typically seen as externalizing. Understanding the normative course of cognitive and brain development as it relates to the development of executive functions will be important elements of a framework that can address issues of disjunction in developmental timing as well as developmental difficulties in regulatory systems per se (Steingard et al., 2002).

A Neuroscience Perspective on Cognitive Development in Adolescence

Until recently, much of the work on adolescent cognitive development was devoted to a search for a core mechanism that could account parsimoniously for the broad changes in adolescent thinking that are observed at a more general level (Keating, 2004). After nearly 50 years of searching, what has emerged instead is the necessity of an integrated account. What lies at the core of adolescent cognitive development is not likely to be any single device that drives it. Rather, it is the attainment of a more fully conscious, self-directed, and self-regulating mind that characterizes the adolescent transition. This is achieved principally through the assembly of an advanced executive suite of capabilities (Donald, 2001) rather than through specific advancement in any one of the constituent elements. This represents a major shift in prevailing views of cognition, going beyond the search for underlying elements (or hidden “demons”; Dennett, 1996) that are formed and operate largely outside of awareness.

The plausibility of such an integrative account has been substantially enhanced by recent major advances in the neurosciences (e.g., Casey, Giedd, & Thomas, 2000; Giedd et al., 1999; Johnson, 2001; Luna et al., 2001; Nelson, 1999; Paus et al., 1999; Sowell et al., 2001; Sowell et al., 2002; Steingard et al., 2002), in comparative neuroanatomy across closely related primate species that illuminate core issues of human cognitive evolution (Donald, 2001; Rilling & Insel, 1999), and in a deepened understanding of the critical role of culture and context in the shaping of cognitive and brain development (Donald, 2001; Francis et al., 2002). Much of the underlying action is focused on specific developments in the prefrontal cortex, but with an equally significant role for rapidly expanding linkages to the whole brain (Donald, 2001; Luna et al., 2001; Newman & Grace, 1999). This complex process of assembly is supported by increasingly rapid connectivity (through continued myelination of nerve fibers), particularly in communication among differ-

ent brain regions, and by significant and localized synaptic pruning especially in frontal areas that are crucial to executive functioning (Giedd et al., 1999; Sowell et al., 2001, 2002; Steingard et al., 2002). In the same way that new research on pubertal processes has made it eminently clear that our understanding of psychopathology in adolescence is not likely to hinge on models that are based on the identification of single-bullet accounts of pubertal maturation, new research on cognitive development in adolescence makes it clear that the search for a unitary aspect of cognitive development in adolescence that explains the onset or course of psychopathology in adolescence is unlikely to bear fruit.

The Role of the Prefrontal Cortex in the Development of Regulatory Competence

It is noteworthy that the most marked differences between adult humans and nonhuman primates (Rilling & Insel, 1999) occur precisely in those features of brain development that emerge most strikingly during adolescence: differentially greater increases in neocortical volume (beyond the expected increase owing to larger brain volume overall); differentially greater gyrification of the prefrontal cortex, indicating a more convoluted design that affords both more capacity for central coordination and more rapid communication; and a greater relative increase in cerebral white matter relative to neocortical gray matter, “suggesting that axonal connections between neocortical neurons may increase faster than the number of neurons as brain size increases” (p. 222). The prefrontal cortex is thus among the latest brain systems to develop, both phylogenetically and ontogenetically, especially the dorsolateral prefrontal cortex (Fuster, 2000). Its importance for adolescent cognitive development can be inferred from this convergence but is more directly evident from its integrative functions. The importance of the relatively late development of systems mediated by the dorsolateral prefrontal cortex is especially important for understanding aspects of psychopathology in adolescence that are somehow related to deficiencies in the coordination of cognitive and affective systems.

The prefrontal lobes have long been seen as central to the coordination of cognitive activity (Case, 1992; Stuss, 1992), whose function is to sustain “many high-level metacognitive operations, such as self-evaluation, long-term planning, prioritizing values, maintaining fluency, and the production of appropriate social behavior” (Donald, 2001, p. 198). The reach and complexity of the prefrontal cortex have been further emphasized in recent work identifying important details of its structure and function

(Barbas & Hilgetag, 2002; Fuster, 2000; Fuster, Van Hoesen, Morecraft, & Semendeferi, 2000; Watanabe, 2002). In particular, the temporal integration of retrospective memory and preparatory set in the dorsolateral prefrontal cortex (Fuster, 2000) creates the conditions for a broader, more fully conscious control of cognition and behavior.

In other words, the narrow window of active awareness that is the focus of much of experimental cognitive science, which seems to undermine assertions of a broader consciousness with significant agency in decision making and planning, captures too little of the important cognitive action (Donald, 2001). In addition, the close connection and communication among regions of the prefrontal cortex that are more cognitive with those that have important linkages with emotional processing, especially the orbitofrontal cortex (Barbas & Hilgetag, 2002), support the view of the prefrontal cortex as a more general synthesizer of experience and governor of action. Thus, the role of the prefrontal cortex as not only an integrator of cognitive functions but also a governing regulator of emotion, attention, and behavior takes on special importance during adolescence in three ways.

First, patterns of individual differences in how cognition, emotion, and behavior become integrated during adolescence may well have a long reach with respect not only to the development of psychopathology but also to normative habits of mind (Keating, 1996a, 1996b, 1996c) that influence trajectories of competence and coping. Second, as already noted, the pubertal influences on many hormonal and neuroendocrine systems are dramatic (Angold et al., 1998), entailing the cascading reorganization of body and brain systems. Third, recent evidence from animal models has demonstrated the partial reversibility of damage acquired during early development, at both the behavioral and the physiological levels, as a function of enriched environments during puberty (Francis et al., 2002). In combination, this evidence points strongly toward both enduring (but not limitless) neural plasticity and the critical role of developmental experience in shaping future developmental trajectories in cognition and behavior (Nelson, 1999; Nelson et al., 2002).

Like early childhood, adolescence may well be a sensitive or critical developmental period for both normative and maladaptive patterns of development through the shaping of future trajectories and in the biological embedding of developmental experiences as the principal method through which this occurs (Boyce & Keating, 2004; Keating & Hertzman, 1999; Meaney, 2001a). Several aspects of development during this period are especially significant in this regard: the interdependence and developmental coordination

of numerous cognitive elements, and of cognition with emotion and behavior; the role of puberty in a fundamental restructuring of many body systems; the apparent concentration of changes in the adolescent brain in the prefrontal cortex (which serves as a governor of cognition and action), together with the enhanced interregional communication between the prefrontal cortex and other brain regions; and the evidence for substantial synaptic pruning and nontrivial physiological reversibility of behavioral and neuroendocrine patterns arising from early developmental experiences.

Taken together, these developments reinforce the emerging understanding of adolescence as a critical or sensitive period for a reorganization of regulatory systems, a reorganization that is fraught with both risks and opportunities for trajectories of psychopathology. A key difference between the early development of regulatory systems that control patterns of arousal and soothing without necessarily invoking cognitive mechanisms and the maturing of regulatory systems in the adolescent transition is the potential for bringing such systems under conscious, self-aware, cognitive control. Recent work from both neuroscience and human evolution supports the view that adolescence is a focal period for this integration of regulatory systems and conscious control. It also supports the view that this developmental integration occurs under the direct influence of the social context, both phylogenetically and ontogenetically.

In a summary of recent work from cognitive neuroscience and evolutionary studies, Donald (2001) proposed three major transitions as levels of consciousness beyond the episodic awareness that we share with our nonhuman primate cousins. Each rests on continuing development and refinement of the executive suite that is concentrated in the prefrontal cortex (including its interregional connectivity): “(1) more precise and self-conscious control of action in mimesis; (2) richer and faster accumulation of cultural knowledge, in speech; and (3) much more powerful and reflective cultures, driven by symbolic technology” (p. 262). Note that each of these proceeds as a coevolution of brain and culture; indeed, the signal species characteristic of *Homo sapiens* can be thought of as cultural mind-sharing that activates individual minds (whose brains have been “designed” by evolution to participate in just such activity). The implication of these convergences is that there exist potentially homologous qualitative transitions in the evolution of the human brain, the nature of primate group interaction, and adolescent cognitive and brain development. The essence of the homology lies in the nature of human consciousness, including its phylogeny, ontogeny, and inseparability from culture and context.

Fully attained human consciousness is thus potentiated by key developments in the brain that are late arrivals in evolutionary history and become fully available for assembly in individual ontogeny only during the adolescent transition. But this potential assembly becomes actual only in close interplay with the surrounding cultural and cognitive web, in which the individual adolescent experiences culture not passively as an external entity, but as an active force (Swidler, 1986) that can be used to both define and achieve goals and serves simultaneously as a fundamental coconstructor of cognition and consciousness.

This coordination of cognitive and cognition-emotion subsystems into a more centrally governed metasystem is thus unlikely to be smooth developmentally or uniform in execution. As we have argued, understanding deviations from optimal developmental pathways will thus require attention to developmental trajectories preceding and subsequent to the adolescent transition, to the fundamental mechanisms of cognitive, emotional, and regulatory systems that are increasingly governed by a centrally coordinated executive system, and to the multiple contexts that constitute the integrated control systems. At the same time that we probe more deeply into neural and neuroendocrine circuitry, to get a full picture, we will need to gain a more precise understanding of the contexts that shape those central developments. It is to the role of context that we now turn.

THE ROLE OF CONTEXT IN THE DEVELOPMENT OF PSYCHOPATHOLOGY IN ADOLESCENCE

Contemporary adolescence is characterized not only by changes within the individual adolescent but also by changes in the contexts in which adolescents live and in their interactions with those contexts. As articulated in ecological models and developmental systems theory (Bronfenbrenner, 1979; Ford & Lerner, 1992; Gottlieb & Halpern, 2002; Thelen & Smith, 1998), individual development is embedded in processes of interaction with family, peers, school, neighborhood, and society. Adolescents in many modern societies spend increasing amounts of time outside the supervision of their parents and in the company of peers, make transitions to secondary schooling, begin to try out the worlds of work and romantic relationships, and engage with media in many forms, often for many hours a week (B. B. Brown & Theobald, 1999; J. Brown & Witherspoon, 2002; Hernandez, 1994; Steinberg & Morris, 2001). The nature of these contexts and

the interactions of adolescents with them have been widely implicated in the development, maintenance, and prevention of psychopathology, although the conceptual models of how and why context and psychopathology may be linked continue to undergo transformation.

Central to the framework advanced in this chapter is the thesis that, during the transition from childhood into adolescence, and over the course of early adolescence in particular, contextual interactions may play a key role in protecting or exacerbating the adaptation of individuals who enter the transition with regulatory vulnerabilities. That is, during early adolescence, a developmental period characterized by a disjunction between arousal activation (which is high) and regulatory competence (which is not yet fully developed), individuals need the assistance and protection provided by a structured and supportive context. In concrete terms, adolescents need the presence of other individuals and institutions that will enable them to develop in healthy ways through a potentially challenging developmental transition by facilitating the development of regulatory competence and protecting from the harmful effects of deficiencies in regulatory skills until these capabilities have matured sufficiently. Concomitantly, this time is particularly risky for young people with little or no contextual support and those with high vulnerability due to regulatory deficiencies.

Context and adolescent psychopathology connections were studied initially in terms of risk factors for psychopathology and problems, such as delinquency, substance abuse, school dropout, depression, eating disorders, and suicidal behavior, all of which were linked in some way to “bad” environments (Dryfoos, 1990; Garnezy, 1983; Lerner & Galambos, 1998; Masten, 1988; Masten & Garnezy, 1985; Repetti, Taylor, & Seeman, 2002). Poor parenting, poverty, divorce, and many other stressful life events, as well as bad neighborhoods and deviant peers were each studied as risk factors for psychopathology. Extensive evidence pointed to unsupportive or dangerous environments and relationships as predictors of psychopathology, although the processes accounting for these outcomes were not well understood. It also became clear that risky conditions often co-occurred, such that some youth faced very hazardous transitions to adolescence, fraught with stressful experiences and little in the way of positive resources; psychopathology was often associated with high net or cumulative risk (Masten, 1988; Masten, Best, & Garnezy, 1990; Masten & Coatsworth, 1998; Rutter, 1979; Sameroff, 2000; Sameroff, Gutman, & Peck, 2003; Yoshikawa, 1994).

With the emergence of developmental approaches to psychopathology, thinking about the connections of context

and adolescent behavior problems has changed in several respects. First, the role of context in normative developmental transitions has received closer examination in efforts to use findings from research on typical development to inform our understanding of maladaptive developmental pathways. Second, more dynamic models of person-environment interaction have gained ground, emphasizing the role of adolescents as agents in the shaping of their own experiences and the importance of relationships in the development and course of problematic and positive behavior during adolescence. Attention is increasingly focused on how contexts and adolescents interact or coact to shape development leading toward or away from psychopathology, with more focus on regulatory processes and concepts such as self-regulation, coregulation, and scaffolding. Finally, there has been a movement away from research on single contexts considered in isolation toward the study of the ways in which multiple, interdependent, and sometimes nested contexts may interact to influence patterns of individual development. These changes reflect the influence of systems theory on conceptualizations of normative and deviant development and also herald an evolving framework for a developmental psychopathology of adolescence.

Over the past 20 years, since Hill (J. P. Hill, 1980, 1983) first published his framework for research in adolescence, there have been marked changes in the study of context in relation to adolescent development, and it is clear that more changes are on the way (Masten, 2001, 2004, 2005, in press; Roberts & Masten, 2005). Studies of traditional contexts, such as peers, families, and schools, continue, but the focus of work has shifted to more complex and dynamic questions. Contexts that had received little study before, including romantic relationships, work, extracurricular activities, and media, are now undergoing more intensive investigation. Emerging technologies have created virtual contexts for adolescent interaction, including electronic friendships, neighborhoods, fantasy worlds, and many other kinds of contexts and contextual interactions. These same technologies have altered the study of context-adolescent interaction as investigators capitalize on computers, cell phones, and pagers to assess the ongoing interactions of adolescents with their environments. This section highlights some of these changes, as investigators try to understand the nature of adolescent interactions with their environments—particularly the interplay of affective systems and context—and how these interactions may contribute to the etiology, maintenance, or prevention of or recovery from psychopathology and other problems in adolescent development.

Several overarching themes in the study of psychopathology and context in adolescence have emerged in the past

decade. First, there is growing evidence that the role of context in the development of psychopathology is typically nonspecific. That is, it is difficult to find links between specific contextual stressors (either chronic or acute) and specific manifestations of dysfunction; divorce, poverty, maltreatment, exposure to neighborhood violence, and peer rejection, for example, are risk factors for many types of problems in adolescence (Steinberg & Avenevoli, 2000). Thus, it appears likely that specificity in the manifestations of emotional and behavioral disorder (i.e., why one individual develops depression but another develops alcohol dependence) likely reflects individual differences (genetic or acquired) in biological diatheses rather than differences in contextual experience.

Second, the impact of contextual stress on psychopathology is cumulative. Individuals whose lives are characterized by a greater number of contextual risks are more likely to show manifestations of internalizing, externalizing, or addictive problems than are those whose lives are characterized by fewer risk factors.

Third, there are significant links among contextual risk factors that make it difficult to study them as independent influences. Adolescents who grow up in dysfunctional family environments, for example, are more likely to experience poverty, attend inadequate schools, encounter antisocial peers, and witness neighborhood violence. By the same token, adolescents who enjoy one form of contextual benefit (e.g., supportive teachers) are also more likely to have lives that are characterized by multiple advantages.

Fourth, contextual risk exerts its impact on psychopathology through both objective and subjective means (Boyce et al., 1998). Thus, in research on context and psychopathology, it is important to document both the objective level of stress and the adolescent's subjective appraisal of it. This is especially important in research involving adolescents from different demographic groups, because the same stressor may be appraised differently by individuals with different backgrounds. What might be considered harsh parenting among middle-class suburban adolescents, for example, may be considered protective among impoverished inner-city youth. To the extent that the impact of parenting is mediated by the way it is interpreted by the adolescent, we would expect that parental strictness would have different effects in these different settings.

Fifth, a complete understanding of the role of context in the development of psychopathology necessitates that attention be paid to the interactive and nested relations among contexts. Until quite recently, investigators focused on one context at a time, such as the family in isolation from the school or neighborhood, or on the peer

group as a context separate from the home or workplace. We know, however, that contexts interact in ways that may exacerbate, compensate for, or cancel out each other's influence on normative and atypical development. Additionally, contemporary research on contextual influence, reflecting the work of Bronfenbrenner (1979) and others, has documented the importance of examining the ways the influence of proximal settings, such as the family, are moderated by factors within the broader contexts that contain them, such as neighborhoods (e.g., Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999; Leventhal & Brooks-Gunn, 2000).

Finally, adolescents are not the passive recipients of contextual influence, but are active agents who choose, transform, and recruit contextual resources. Unlike younger children, who have little control over where and with whom they spend time, adolescents are more active in selecting the contexts to which they are exposed; although adolescents have little say over their family or school environments, they choose their friends, decide whether to work or engage in extracurricular activities, and pick the media to which they are exposed. This fact poses a challenge to researchers interested in demonstrating causal influences of context on psychopathology, because often it is not clear whether it is the context that is driving the psychopathology or the reverse. Thus, for example, the links between externalizing problems and affiliation with antisocial peers may result from the self-selection of antisocial adolescents into deviant peer groups as well as the recruitment of alienated youth into deviant groups. Deviant peer association may then function to exacerbate antisocial behavior through reinforcement, modeling, opportunities, or combined influences of this kind. It is not easy to sort out causality when there is so much reciprocal influence. In addition, and operating above and beyond any selection process, is the fact that adolescents actually influence their parents, friends, teachers, and neighbors in ways that affect the home, peer, school, and community contexts, which then, in turn, influence the adolescent's development. An important but understudied issue is how, under what circumstances, and through what processes adolescents actively employ contextual resources (from relationships with parents, friends, and teachers to video games and Internet chat rooms) as a means of protection against the adverse effects of environmental stress and for the amelioration of psychological distress.

A detailed review of the vast literature on specific aspects of context that have been associated with various forms of psychopathology in adolescence is beyond the scope of this chapter. In the sections that follow, we high-

light points of consensus and areas of converging evidence in different contexts.

The Role of the Family

Of the many contexts that have been studied in relation to adolescent psychopathology, none has received as much attention as the family. Parent-adolescent relationships characterized by warmth, support, age- and context-appropriate monitoring, and clear expectations for positive behavior—the kind of parenting known as “authoritative” in style (Baumrind, 1973, 1991)—continues to be widely associated with positive adaptation in adolescence (Steinberg, 2001). Conversely, families that provide little warmth, structure, or resources or that expose the adolescent to high levels of hostility may not only exacerbate risk for psychopathology, but also fail to scaffold successful transitions in adolescence, leaving their adolescent children unprotected during a challenging time of change (Ge, Lorenz, Conger, Elder, & Simons, 1994; Masten, 1988; Repetti et al., 2002). If is, of course, quite possible that parents who do not function well transmit genetic vulnerability to psychopathology along with providing a risk-laden or neglectful environment. This is a classic confound in diathesis-stressor models of psychopathology, and the issue has reemerged in contemporary debates about the importance of parenting in development (Collins, Maccoby, Steinberg, & Hetherington, 2000; Masten & Shaffer, *in press*; Repetti et al., 2002; Scarr & McCartney, 1983).

Nonetheless, research implicates parenting as a key mediator of adverse life experiences and psychosocial disadvantage on adolescent behavior (Bradley & Corwyn, 2002; Elder & Conger, 2000; McLoyd, 1998; Sampson & Laub, 1994; Yoshikawa, 1994). In these models, with compelling supportive data, adversity undermines parental functioning, which in turn affects adolescent functioning. Not surprisingly, adolescents who achieve more positive adaptation in the presence of adversity or psychosocial risk often have better-functioning parents or other adults who provide effective parent resources for them in spite of high-adversity exposure (Masten, 2001; Masten et al., 1999). Recent studies also hint at the potential role of parenting in scaffolding self-regulation skills in the transition to adolescence; in a recent study of competence development among rural African American adolescents living in poverty, the effects of effective parenting on competence in young adolescents was mediated by self-regulation in the adolescents (Brody, Murry, Kim, & Brown, 2002). Moreover, interventions to facilitate or protect the quality of parent functioning under adverse conditions appear to be effective in altering the risk for prob-

lems developing in children and adolescents (Forgatch & DeGarmo, 1999; Hawkins et al., 2003; Tremblay, Vitaro, Nagin, Pagani, & Séguin, 2003; Wolchik et al., 2002).

Recent studies of families also focus on indirect and possible long-term effects that families may have in protecting or harming development in adolescence indirectly, through their influence on the opportunities, peers, schools, and neighborhood resources available to their children. Long before the challenges of adolescence arrive, effective parents may facilitate the successes of their children in peer relations and schools, indirectly increasing the likelihood of bonding to prosocial peers and school engagement that may be a key to avoiding increases in antisocial and other risk-taking behaviors that tend to accompany transitions to adolescence (B. B. Brown, Mounts, Lamborn, & Steinberg, 1993; Collins et al., 2000; Galambos, Barker, & Almeida, 2003; Pettit, Bates, Dodge, & Meece, 1999; Wagner & Reiss, 1995).

It is also interesting to note that normative data on changes in adolescent-parent interactions through the transitions of early adolescence suggest some kind of transformation in coregulation within these relationships. A meta-analysis of studies of parent-adolescent conflict indicates that although conflict generally declines across adolescence, the intensity of affect characterizing these conflicts rises in early adolescence (Laursen, Coy, & Collins, 1998). Sufficient data are not yet available to discern subtle patterns or differentiate age, context, and pubertal effects in these parent-adolescent interactions. However, studies do corroborate the general idea prominent in many theories of adolescent maturation that reorganizations occur in parent-adolescent interactions around adolescence and that these transformations involve affect regulation. It is therefore important to understand how variations in parenting practices may contribute to the development of regulatory competence.

Peers as Positive and Negative Influences on Adolescent Development

In most modern societies, adolescents spend more unsupervised time in the company of their peers than do younger children, and it is widely accepted that peers play an increasing role in the lives of adolescents as compared to younger children (B. B. Brown & Theobald, 1999; Bukowski, Newcomb, & Hartup, 1998; Collins & Laursen, 1999; Hartup, 1996; Hartup & van Lieshout, 1995; Parker, Rubin, Price, & DeRosier, 1995; Steinberg & Morris, 2001). As children grow older, they typically have more freedom of choice about whom they associate with. Adolescents may choose peers who reinforce their own beliefs, enable them to explore new

roles, or engage in exciting activities. They also may be recruited by peers for similar reasons. Thus, peers have increasing potential as part of the regulatory systems available to adolescents. Adolescents may self-regulate by actively seeking peer interactions; peers also may deliberately act to cheer up, calm down, or recruit a friend for illicit activities. Evidence suggests that adolescents actively select peer contexts that reflect their personalities or preferences and that peer groups in turn influence adolescents' mood states and behavior (B. B. Brown & Theobald, 1999; Cairns & Cairns, 1994; Collins et al., 2000; Dishion & Patterson, this *Handbook*, Volume 3; Tremblay et al., 2003). Teens in the popular groups at some high schools appear to have increased risk for substance abuse problems (B. B. Brown et al., 1993). In the Michigan Study of Adolescent Life Transitions (see Eccles, Barber, Stone, & Hunt, 2003), male and female seniors involved in team sports (often among the most popular youth in high school) reported more alcohol use and drinking problems than nonathletes, despite better academic achievement, enjoyment of school, and subsequent educational and occupational success. With respect to psychopathology, antisocial behavior can lead to rejection by normative peers in middle childhood and also to affiliation with deviant peers, who subsequently encourage negative behaviors ranging from delinquent activities to health-risk behaviors (Catalano & Hawkins, 1996; Deater-Deckard, 2001; Dishion, Andrews, & Crosby, 1995; Dodge & Pettit, 2003; J. P. Hill, 2002; Parker et al., 1995; Patterson, Reid, & Dishion, 1992; Tremblay et al., 2003). Other children may withdraw from social interaction with peers due to shyness or anxiety and become more lonely and sad as a result (Deater-Deckard, 2001; Rubin & Bukowski, 1998). It is interesting to note that anxious solitude may contain the growth of antisocial behavior in adolescence, suggesting that this variable (likely reflecting high inhibition or social anxiety) may function as a risk factor for internalizing problems and a protective factor for externalizing problems (Masten et al., in press; Mesman, Bongers, & Koot, 2001; Moffitt, Caspi, Harrington, & Milne, 2002; Pine, Cohen, & Cohen, 2000).

Peer-Family Joint Effects

One of the advances in the study of peer and family contexts in recent years has come in the form of considering how each of these systems may influence the effects of the other. Poor parenting may elevate the risk for association with deviant peers; concomitantly, lack of monitoring may increase unstructured time with antisocial peers, facilitating "deviancy training" (Bogenschneider, Wu, Raffaelli, & Tsay, 1998; Deater-Deckard, 2001; Dishion, McCord, & Poulin, 1999;

Parker et al., 1995). Peer relations have been found to increase the influence of negative parenting on externalizing behavior (Lansford, Criss, Pettit, Dodge, & Bates, 2003). On the positive side, close parent-adolescent relationships may enhance the likelihood of exposure to positive peer networks as well as the socioemotional skills to engage effectively with peers (B. B. Brown & Theobald, 1999; Collins et al., 2000; Sroufe, Egeland, & Carlson, 1999). Evidence also suggests that good-quality relationships with parents may moderate the influence of deviant friends (Galambos et al., 2003; Vitaro, Brendgen, & Tremblay, 2000).

Romantic Relationships

Another change evident over the past 20 years is the increasing attention to romantic relationships as contexts for adolescent development (Collins & Laursen, 1999; Furman, Brown, & Feiring, 1999; Steinberg & Morris, 2001). Romantic relationships emerge in adolescence, though they may remain exploratory until early adulthood; this domain can be conceptualized as an emerging developmental task in adolescence and a salient developmental task of early adulthood (Roisman, Masten, Coatsworth, & Tellegen, 2004). These special peer relationships, spurred by new motivational systems, pubertal processes, and a culture promoting adolescent sexuality and romance, offer a new realm of possibilities for adolescents to experience emotional extremes of happiness, excitement, disappointment, and despair. Romantic feelings appear to be powerful activators of behavior; concomitantly, romantic relationships appear to be powerful regulators of arousal and affect (Furman et al., 1999; Larson, Clore, & Wood, 1999; Maccoby, 1998; Richards et al., 1998). We noted previously that early maturing is a risk factor for a variety of problems; for some girls, this risk appears to be mediated by romantic relationships with older boys (Steinberg & Morris, 2001). Breakups of romantic relationships also may trigger great distress in adolescents (Larson et al., 1999). Recent work based on sexual selection theory suggests that peer group dominance among males and relational aggression among females are related over time to dating popularity in young adolescents (Pellegrini & Long, 2003). Though still limited, the growing literature on romantic relationships in adolescence suggests that these relationships may play complex roles in social development and the regulation of affect, with positive and negative ramifications.

Schools and Psychopathology in Adolescence

School contexts play a salient role in the lives of modern youth for many years and in multiple ways. The transition to

secondary schooling in adolescence presents new challenges and opportunities for learning, peer relationships, extracurricular activities, and having fun, with all the attendant complexities of cognitive, emotional, social, and cultural processes (Entwisle, 1990; Roeser, Eccles, & Freedman-Doan, 1999; Roeser, Eccles, & Sameroff, 1998, 2000). Substantial progress has been made in documenting the significance of schools in the lives of adolescents (Blum, McNeely, & Rinehart, 2002; Eccles & Roeser, 1999; Hawkins, Catalano, Kosterman, Abbott, & Hill, 1999; Roeser, Eccles, & Sameroff, 1998, 2000; Stipek, 1997). Transitions into junior high school and high school often are accompanied by normative changes in motivation, attendance, involvement, and achievement.

Psychopathology has been linked to school failure and disengagement in various ways. For example, adolescents who are antisocial, anxious, or depressed may not go to school or perform well when they get there; academic failure may increase the likelihood of dropping out, affiliation with deviant peers, or internalizing symptoms; or youth may be victimized at school (Masten et al., in press; Roeser et al., 2000; Stipek, 1997). Perhaps the most striking conclusion to be drawn from recent studies of competence in the school context and either externalizing or internalizing symptoms in adolescence is the *salience* of academic success or failure as a mediator, outcome, and predictor of adolescent symptoms and disorders (Elder & Conger, 2000; Hawkins et al., 1999, 2003; Hinshaw, 2002; Maguin & Loeber, 1996; Masten, 2003, in press; Masten et al., 1995, in press; Roeser et al., 1999; Roeser, Eccles, & Strobel, 1998; Stipek, 1997).

Interventions to promote positive bonding to school and academic achievement have shown success, increasing academic attainment and reducing dropout and delinquency. The mediating processes by which these interventions work are not well understood, though increasingly, interventions are designed strategically to shed some light on the mediating processes. Hawkins et al. (2003), in the Seattle Social Development Project, have shown that multifaceted elementary school interventions increase positive bonding to school in the high school years, which is associated with school success and lower risk for multiple problems. A study of mentoring as an intervention by Rhodes, Grossman, and Resch (2000) suggested that the Big Brother Big Sister program improves relationships with parents along with school involvement and achievement. Mentoring may have some direct influences on school values and behavior, but these interventions also may provide indirect benefits in the lives of adolescents that are mediated by parent-adolescent relationships.

Recent attention also has focused on the role of extracurricular activities in adolescent development (Mahoney, 2000). Such activities may provide opportunities for triumphs and risk for tragedies, but also may serve the more mundane but important function of bonding youth to the normative school context and normative peers, with important socialization sequelae. Little is known about the general regulatory role sports and other activities may play in the healthy development of adolescents, though studies of the joys and stresses of sport involvement suggest intense possibilities for affect regulation, for good or ill (Gatz, M., Messner, & Ball-Rokeach, 2002; President's Council on Physical Fitness and Sports, 1997; Smoll & Smith, 2002). Structured activities of diverse kinds could play a powerful regulatory role in stress management and arousal regulation, may help adolescents acquire self-control and related regulatory competencies, and may serve to facilitate relationships with peers and coaches who can also play such regulatory roles.

Work as a Context for Adolescent Development

The role of the work context in adolescent development and psychopathology has also seen increased research over the past 20 years (Mortimer, 2003; Mortimer & Staff, in press; Roisman et al., 2004; Steinberg & Morris, 2001). Considerable attention has been given to the question of relative risks and benefits of work. In terms of psychopathology or positive adaptation, work may exacerbate stress and distress, increase self-efficacy, take time from schoolwork, or motivate youth to success in school. Generally, moderate work hours in the lives of ordinary adolescents who are succeeding in other aspects of their lives appears to have at least short-term benefits (e.g., extra money and self-confidence) and few costs. For some youth, steady low-intensity work during adolescence may also have long-term benefits in vocational development (Mortimer, 2003). However, working long hours at unskilled jobs may contribute to symptoms, either directly (stress) or indirectly, by contributing to school problems.

The extent to which work may contribute to regulatory competence likely depends on the nature of the work environment, the number of hours per week the adolescent works, and the extent to which working facilitates or interferes with the successful negotiation of other tasks, such as those affecting achievement in school (Roisman et al., 2004). In an appropriately challenging job with adequate supervision, where the adolescent is acquiring skills and not unduly stressed by demanding work hours, employment may contribute to the development of responsibility, time

management skills, and self-confidence. In a menial job with inadequate supervision, where work is stressful and hours long, however, employment may contribute to mental health problems, alcohol and drug use, and diminished attachment to school (Staff, Mortimer, & Ugen, in press).

Community, Society, and Culture

One of the marked changes characteristic of adolescence in many modern societies is the increased level of mobility in society and the potential for engaging and being engaged by more aspects of community, culture, and society outside the family and school contexts. Recent studies have begun to address the potency of neighborhoods as sources of risks, assets, and moderators of adolescent development (Duncan & Raudenbush, 2001; Leventhal & Brooks-Gunn, 2000; Lynam et al., 2000; Sampson, Morenoff, & Gannon-Rowley, 2002; Sampson, Raudenbush, & Earls, 1997; Sampson, Squires, & Zhou, 2001). There are hints in this literature that social structures in neighborhoods may function as regulatory systems for the behavior of youth, although it is difficult methodologically to sort out the role of larger social systems from the influence of the individuals and families that compose them (Duncan & Raudenbush, 2001). Studies of resilience in youth at risk due to family adversity or poverty suggest that external regulatory systems in communities (provided by churches, boys' and girls' clubs, recreational centers and teams, etc.) may play a protective role for the development of competence (Masten & Coatsworth, 1998). Who chooses to engage such systems and why remains an intriguing mystery. Coaches and youth ministers may seek out youth, youth may seek out competent and trustworthy adults, or juvenile systems may assign youth to some of these connections. Yet, for these external systems to work, adolescents must participate, and it seems likely that the bonding of youth to positive community systems is scaffolded through the relationships they form with mentors and other program participants.

Macrosystem influences on the regulation of adolescent risk behavior and, accordingly, vulnerability to certain forms of psychopathology also are beginning to be studied. Examples include studies of cigarette tax policy on adolescent tobacco use (Flay & Petraitis, 1994), the impact of gun-control policies on access to weapons (Elliott, Hamburg, & Williams, 1998), the effects of condom distribution in school-based health clinics, and the impact of graduated driver's licensing policies on automobile accidents. Although these policies are rarely thought of as interventions designed to prevent or reduce psychopathology, they can be viewed as attempts to impose external regulation on individuals whose judgment and regulatory compe-

tence is not yet fully mature. One interesting but unstudied question is the relative effectiveness of policies designed to impose regulatory control on adolescents as a means of limiting risk behavior versus those designed to limit risk behavior by increasing adolescents' regulatory competence (e.g., through educational intervention).

Media and Virtual Contexts

Whereas many of the traditional contexts of adolescence development—involving family, peers, school, neighborhoods, and work—readily fit an embedded systems model of development, as proposed by Bronfenbrenner (1979) and others, other elements of context in adolescents' lives do not fit so neatly. Yet, these experiences may play an enormous and growing role in adolescent development. In particular, music, movies, and television, as well as the new virtual worlds of electronic games, web sites, and Internet chat rooms, saturate the lives of many adolescents many hours a day, penetrating most other contexts of interaction. The “media diet” (J. D. Brown, 2000; J. D. Brown & Witherspoon, 2002) of American teenagers reflects a rapidly changing and increasingly individualized context for learning, self-regulation, victimization, friendship formation, sex, violence, illegal activity, and self-discovery, among other processes. Teenagers clearly utilize music, phones, movies, games, chat rooms, instant messaging, e-mail, and other electronic media to meet all kinds of needs. Increasingly, these media can be tailored to individual desires, so that adolescents can fine-tune their own experiences. Concomitantly, the same strategies can be utilized by marketers to recruit teenagers as consumers, often with the promise of happiness or sex appeal through consumption of food or drugs or the purchase of goods and services. The role of these transactions in the development or avoidance of psychopathology, misery, antisocial behavior, or risk-taking behavior is only beginning to be considered, as concern grows about the unmonitored interactions of adolescents through these media on violence, depression, self-injury behavior, substance use, and many other problems or risky behaviors.

New Approaches to Context in Relation to Adolescent Psychopathology: A Summary

Over the past 20 years, there has been a rapid expansion of research and theory on the significance of context-adolescent interactions for adolescent development and psychopathology. Work and romantic relationships have gained more attention, as have the moderating and mediating roles

of one context in regard to another. A profound change has occurred in the conceptualization of context in relation to adolescent development. Relationships, media, drugs, food, and activities, for example, are viewed as ways for adolescents to develop and exercise regulatory competence and to modulate levels of negative affect.

Our point is that adolescents recruit context to regulate their emotion, arousal, motivation, and behavior, sometimes deliberately and sometimes without any awareness of the process. To manage their affect, thoughts, and actions, adolescents listen to music, phone their friends, pick fights with their parents, ask romantic partners for advice, meet their classmates at coffee shops, drink alcohol at parties, play basketball, or go dancing. Conversely, contexts actively recruit adolescents. As adolescents in modern societies gain economic influence, more and more films, television program, games, clothes, drugs, food, and consumer products are marketed to them, often blatantly advertised for the purpose of regulating mood or arousal. In relationships and in virtual worlds of interactions, friends, romantic partners, and strangers may have ample opportunity to engage in coregulation of each other's affect and behavior.

Concerns about deviant outcomes from adolescent-context interactions have increased, perhaps in part as a function of the decreasing control of adults over these transactions. Major concerns include social contagion of maladaptive behaviors, such as violence, self-injury, depression, or suicide. On the other hand, emerging contexts for adolescent development, such as virtual friends and support networks, could conceivably offer just as many positive as negative opportunities (J. D. Brown & Witherpoon, 2002). The extensive and expanding contexts available to adolescents may be challenging and overwhelming or supportive and protective.

As adolescents, who might be viewed as novice adults, negotiate the many changes of adolescence and the transition to self-regulated behavior, they may call on people in the various contexts of their lives for help. At the same time, adults, especially parents, may deliberately scaffold this long-term transition to adulthood through provision of adequate structure, support, and opportunities to facilitate success. If developmental decalage occurs, with major differences in the functional maturity of affective, sexual, cognitive, and social systems utilized by adolescents to adapt, resources in the external context, in relationships, and in formal and informal institutions may provide compensatory or protective effects that temporarily close the functional gaps in emotional and cognitive maturity with and across individuals. Conceptualizing the role of context

in this way may offer important perspectives for interventions to prevent and ameliorate behavioral and emotional problems in adolescence.

CONCLUDING COMMENTS AND FUTURE DIRECTIONS

The framework we have advanced in this chapter articulates a new view of psychopathology in adolescence that is grounded in an emerging understanding of the ways neurobiology and context interact during the transition from childhood to adulthood. This framework begins from the premise that adolescence is characterized by an increased need to regulate affect and behavior in accordance with long-term goals and consequences, often at a distance from the adults who provided regulatory structure and guidance during childhood. From this vantage point, adolescence is a time of especially heightened vulnerability to psychopathology specifically as a result of disjunctions between and among developing brain, behavioral, and cognitive systems that mature along different timetables and under the control of both common and independent biological processes. These disjunctions, in turn, create gaps between affect, thinking, and action. Viewed from this perspective, symptoms of various types of psychopathology in adolescence can be profitably understood as reflecting difficulties in the coordination of emotional, intellectual, and behavioral proclivities, capacities, and capabilities. By all indications, adolescence may well be a sensitive or critical developmental period for both normative and maladaptive patterns of development through the shaping of future trajectories and in the biological embedding of developmental experiences as the principal method through which this occurs.

Although adolescence is a time of increased vulnerability to psychological dysfunction, the fact remains that only a minority of adolescents develop psychopathology. To be useful, then, any framework that purports to aid in our understanding of psychopathology in adolescence must account not only for the heightened vulnerability that is characteristic of the period in general, but also for the wide variability between individuals in whether and to what extent this vulnerability is ever actualized. Virtually all adolescents will experience the sorts of disjunctions between affect, cognition, and behavior to which we have alluded, but most individuals will weather these difficulties and move into adulthood having experienced no or few serious difficulties.

In our view, individual differences in emotional and behavioral dysfunction during this period inhere in differences among adolescents in the nature and extent of these

disjunctions and in the availability of contextual support and the presence of contextual risk during times of heightened neurobiological vulnerability. Research on early maturing girls is a case in point. As we have noted, for example, early maturing girls are, on average, at greater risk for the development of emotional and behavioral problems than their on-time or late-maturing peers. This is likely because earlier pubertal maturation brings with it changes in arousal that precede, by a fairly long stretch of time, the development of the regulatory competence necessary to modulate these drives; this is the sort of disjunction between arousal and regulatory competence that heightens vulnerability to problems. Moreover, the physical changes that accompany puberty also elicit new interactions with context (e.g., attracting attention from older peers and unwelcome advances from adult strangers) that may be difficult for a young girl to handle. Yet, most early maturing girls do not develop psychopathology. This is because early puberty is a risk factor for psychopathology among adolescent girls only under conditions of specific contextual risk: in families that expose the adolescent to stressful life events, in schools in which older boys are present, in communities in which students are especially body conscious, and in cultures that place a premium on thinness (Steinberg, 2005).

The past 2 decades have seen considerable progress in our understanding of the most important sources of contextual risk and support. We now have a very good sense of what adolescents need in the family, school, peer, and neighborhood contexts to maximize positive youth development and minimize emotional and behavioral problems. There is an especially rich literature on familial risk and protective factors and, to a lesser extent, on the influence of peer, school, and work settings. Overall, the study of environmental influence on psychopathology in adolescence has yielded a solid basis for the development of preventive interventions and treatments, but research has focused largely on the influence of family and friends, and much work remains to be done on understudied contextual influences, such as those of romantic partners, neighborhoods, and electronic media.

In contrast to our understanding of the role of context in the development of psychopathology, considerably less is known about the neurobiological factors—both genetic and acquired, individual-specific and developmentally universal—that place individuals at risk for psychopathology as they move into and through adolescence. Scholars have long recognized that the biological changes of adolescence must play some role in the development of disorder, but until recently, this recognition has been largely nonspe-

cific. There is no doubt that today we are on the cusp of a biological revolution in the study of normative and atypical adolescent development—a revolution made possible by tremendous advances in the study of molecular genetics, endocrinology, neurotransmission, and structural and functional brain anatomy. These advances will enable the field to move beyond sweeping generalizations about the significance of puberty or of changes in certain brain regions in the development of psychopathology in adolescence and to begin to identify the specific aspects of pubertal maturation and brain development that are linked to specific forms of psychological malady. This will require a careful unpacking of puberty as a multifaceted phenomenon that involves endocrinological, neuroendocrinological, somatic, and social processes and an equally careful unpacking of brain development in adolescence that links maturational change within and across specific systems (note: *systems*, not regions) to changes in behavior, cognition, and affect.

Recent breakthroughs in neuroscience generate considerable enthusiasm for expanding knowledge on the mechanisms behind adolescent changes in behavior associated with successful or unsuccessful transitions in development. Although this process is widely known to be regulated by multiple factors acting across various levels, recent studies have begun to delineate the nature of such interactions. For example, specific genetic factors have been shown to moderate developmental trajectories following exposure to trauma (Caspi et al., 2002, 2003). Such concrete demonstrations of interactions between genetic and environmental factors provide insights for future work. Further studies are needed that delineate other examples of interactions between genetic or other person-specific factors and environmental factors as mediators of the adolescent transition. Moreover, following successful demonstration of such interactions, experimental studies are now needed that examine the effects of targeted manipulations on long-term outcome. For example, given evidence of gene-environment interactions, interventions designed to remove potentially noxious environmental effects might be expected to have more potent effects on one or another subgroup of adolescents. Finally, documenting interactions between genes and environments should increase efforts to delineate the path that extends from genetics to behavior, a path that must ultimately involve changes in specific neural circuits. Advances in neuroimaging techniques provide the tools for delineating relevant functional, developmental changes in underlying neural circuits that occur during adolescence (McClure et al., 2004; Monk et al., 2003; Pine et al., 2002, 2004). For such techniques to be used most effectively, further work is needed developing experimental paradigms

sensitive to relevant behavioral dimensions manifest in the laboratory.

It is a well-worn cliché to note that progress in the study of psychological development, whether normative or atypical, will require interdisciplinary collaboration among scholars trained in different disciplines. But like all clichés, this one has many elements of truth to it. Despite its obvious importance, the biological revolution that is currently unfolding in the study of adolescence will not suffice in the search for a complete understanding of the development, prevention, and treatment of psychopathology during this stage of life. Biological vulnerabilities may set the stage for psychopathology, but they by no means determine its course. Biological vulnerabilities expressed in different contexts often lead to vastly different outcomes.

Nor will the answer to questions about the onset, nature, and course of psychopathology be found in the study of context alone. We have noted numerous times in this chapter that the sources of contextual risk and protection in adolescence are nonspecific and cumulative. A wide variety of risk and protective factors are associated with the presence or absence of a wide range of difficulties, and the likelihood of psychopathology increases as a function of the sheer number of risk factors in the individual's environment and decreases as a function of the sheer number of protective factors.

Future progress in the developmental psychopathology of adolescence demands an integration of research on brain, behavior, and context. This will require cross-training and collaboration of scientists who specialize in neuroscience, behavioral development, and influential contextual systems, including families, peers, communities, media, policy, and multiple aspects of culture. In this chapter, we offer a framework that we hope will launch many such efforts.

Brain development occurs along a complex yet systematic schedule dictated by a combination of genetic and epigenetic influences (Rubenstein & Rakic, 1999). Prenatal gray matter development is marked by rapid neurogenesis resulting in a proliferation of redundant synaptic matter during early postnatal development (Huttenlocher & Dabholkar, 1997). Redundant synaptic matter is subsequently pruned during the course of childhood and adolescence, reflecting a functional coupling between interactions with the environment and neurodevelopment (Lund, 1997). White matter development follows a complementary course with early postnatal myelination observed in the pons and the cerebellum, followed by myelination in the corpus callosum and its subregions and finally in white matter in the heteromodal association regions (van der Knaap & Valk, 1990). Neurodevelopment is a continuous process; in the absence of derailments due to deep or subtle pathology, the resultant output of these vastly complicated and interdependent processes of genetically driven development and sensory innervation is a brain that is balanced both in terms of its structural organization and in its functional specification

(Laughlin & Sejnowski, 2003; Rakic, 1999). However, this delicate balance is vulnerable to pathological insults that may have diverse origins.

BACKGROUND: NEURODEVELOPMENT

Neuropsychiatric illnesses are increasingly thought to result from processes of abnormal neurodevelopment at critical stages of the individual's growth (Lewis & Levitt, 2002; Marenco & Weinberger, 2001; Nasrallah, 1997). Several lines of evidence suggest this. Psychopathological signs of abnormal behavior are evident before the onset of frank psychosis, particularly during adolescence, and may be predictive of the onset of illness (Aarkrog & Mortensen, 1985; Keshavan, 1999; Keshavan, Dick, et al., 2002; Keshavan, Stanley, Montrose, Minshew, & Pettegrew, 2003; Montrose et al., 1997; Winters, Cornblatt, & Erlenmeyer-Kimling, 1991). A handful of cross-sectional and longitudinal studies have documented progressive changes in brain structure during adolescence in illnesses such as early-onset Schizophrenia, including accelerated ventricular expansion and cortical gray matter loss (Gogtay et al., 2003; Rapoport et al., 1997, 1999). Studies of young populations at genetic risk for illnesses such as

This work was supported in part by NIMH grants 68680 (VAD), 64023, 01180 (MSK), a NARSAD Young Investigator award (VAD), and a NARSAD Independent Investigator award (MSK).

Schizophrenia point to abnormal brain morphology and function of crucial cortical structures such as the prefrontal cortex and the superior temporal cortex that are qualitatively similar to those observed in first-episode patients (Job et al., 2003; Keshavan, Dick, et al., 2002; Keshavan et al., 2003). These and other lines of evidence motivate the search for developmental correlates of neuropsychiatric illnesses that may result from complex interactions among genetic predispositions, the environment, and alterations in programmed neurodevelopment (Lewis & Levitt, 2002; Tsuang, 2000).

Clearly, any number of facets of neurodevelopment may be studied to examine their impact on neuropsychiatric illness. The majority of studies have focused on changes in the trajectory of gray matter development measured using high-resolution magnetic resonance imaging (MRI), probably because synaptic (i.e., gray matter) activity is associated most closely with cognition and behavior. Furthermore, as mentioned earlier, the profile of gray matter change starting with synapse production and continuing on through neuronal and synaptic pruning during adolescence has been well established by experimental methods ranging from tissue analysis to analyses of *in vivo* MRI (Gogtay et al., 2004; Sowell, Thompson, Tessner, & Toga, 2001; Webb, Monk, & Nelson, 2001). Finally, accelerated synaptic pruning during adolescence (Feinberg, 1990; Keshavan, Anderson, & Pettegrew, 1994) is an important explanation for widespread reductions in cortical gray matter volume that have been reported in neuropsychiatric illnesses such as Schizophrenia and Bipolar Disorder (Lim, Rosenbloom, Faustman, Sullivan, & Pfefferbaum, 1999; Lyoo et al., 2004; Shenton, Dickey, Frumin, & McCarley, 2001). However, recent paradigm shifts have led to a departure from a focal lesion(s) model of neuropsychiatric illness to a view of these illnesses as being disorders of connections between brain regions. Therefore, there has been an increasing interest in the development of white matter and the role that altered white matter expansion or connectivity may play in psychiatric illnesses and disorders.

The maturation of white matter in the brain follows an orderly pattern that has been elucidated in both the early postnatal phase and through adolescence using MRI (Barkovich, 2000). Qualitative analyses have indicated early myelination in subcortical structures such as the pons and the cerebellar peduncles, followed by the internal capsule, the corpus callosum, and finally in corticocortical white matter tracks (Barkovich, Kjos, Jackson, & Norman, 1988; Barkovich & Maroldo, 1993; Girard, Raybaud, & du Lac, 1991; McCardle et al., 1987; van der Knaap & Valk,

1990). A significant increase in the absolute volume of cortical white matter has been reported through adolescence and young adulthood (Giedd, Blumenthal, Jeffries, Castellanos, et al., 1999), with an increase in white matter density particularly prominent in structures such as the internal capsule that may be associated with an expansion in motor and linguistic capacity in this period (Paus et al., 1999). White matter expansion in conjunction with programmed gray matter loss continues into young adulthood, by which time the ratio of cortical gray to white matter asymptotes, signaling a large degree of stability in the structural organization of the brain (Pfefferbaum et al., 1994). It is the simultaneous decrease of metabolically expensive gray matter along with the increase of metabolically inexpensive white matter that results in an “optimized” ratio of gray to white matter (Zhang & Sejnowski, 2000). As with cortical folding, the corticocortical connectivity provided by white matter connections enables the efficient computation and transfer of information in spite of the brain’s limitations of finite volume (Karbowski, 2003). MRI investigations in the primate brain have revealed that the rate of increase of cerebral white matter expansion outpaces that in neocortical gray matter (Rilling & Insel, 1999), indicating the fundamental role of developmentally driven white matter expansion in cortical organization. Through this connective network, neuronal impulses are efficiently conveyed between cortical and subcortical regions that have been endowed with relative specialization for particular tasks through evolution. It is largely this interregional and interhemispheric communication that makes higher-order cognitive activity possible (Gazzaniga, 1989; Goldman-Rakic, 1988). Disturbances in communication are most likely to give rise to disturbances in higher-order cognitive processes that are the hallmark of many neuropsychiatric disorders (Lee, Williams, Breakspear, & Gordon, 2003).

Many neuropsychiatric illnesses such as Schizophrenia and Bipolar Disorder are marked by disordered thought and persistent cognitive impairment. These impairments in higher-order functions are among the core symptoms of these disorders and are thought to be predictive of outcome (Kuperberg & Heckers, 2000). Cognitive symptoms include impairments in social cognition (Insel & Fernald, 2004), lowering of working memory capacity (Goldman-Rakic, 1994), loss of executive control and planning, and impairments in attention (Elvevag & Goldberg, 2000; Quraishi & Frangou, 2002). The widespread pattern of these cognitive symptoms (particularly in Schizophrenia) suggests more than simply focal impairments to a few cortical structures. Rather, they suggest a fundamental

dysfunction in the integrity of neuronal networks in the brain. This pattern of observed cognitive impairment has in part given rise to “disconnection hypotheses” (Friston, 1998; McGlashan & Hoffman, 2000), which suggest that neuropsychiatric illnesses arise not from focal insults to specific regions of interest in the brain, but imbalances in neural circuitry (Grossberg, 2000). This implies that it is not gray matter alone but also abnormal white matter that may be a core correlate of neuropsychiatric illnesses (Lim & Helpert, 2002), motivating the need to identify structural and functional impairments in cortical and sub-cortical white matter. Of the white matter structures in the brain, the corpus callosum is perhaps the most important from the perspective of its function, structure, and development.

THE CORPUS CALLOSUM: DEVELOPMENT AND INFORMATION PROCESSING

The corpus callosum is the principal commissure connecting the right and left hemispheres of the brain. The structure (most clearly visible in a midsagittal MRI section; see Figure 19.1a) consists of packed bundles of white matter fibers arranged along the midbrain and connecting the hemispheres. Developmental increases in callosal size are largely related to increases in axonal size and myelination (S. Clarke, Kraftsik, Van der Loos, & Innocenti, 1989); therefore, illnesses that may be associated with abnormal axonal size, number, or myelination, such as Schizophrenia, may be particularly vulnerable to callosal pathology.

The corpus callosum remains largely responsible for the interhemispheric integration of sensory, motor, and cognitive experiences (Seymour, Reuter-Lorenz, & Gazzaniga, 1994), and its developed nature is thought to largely enable conscious experience and performance (Diamond, 1976; Gazzaniga, 2000). In addition, fibers in the corpus callosum are topographically organized along an anterior to posterior scheme (Figure 19.1b). As shown, the callosum can be divided into subdivisions: the genu, the body, the isthmus, and the splenium. Postmortem tissue analyses have revealed systematic associations between callosal subregions and interconnectivity between hemispheric regions as Wallerian degeneration in callosal subregions are associated with specific cortical lesions due to infarctions or contusions. Degeneration of the genu was associated with prefrontal cortical infarctions, the body with temporoparietal infarctions, and the splenium with temporo-occipital infarctions (deLacoste, Kirkpatrick, & Ross, 1985). These and other investigations in humans and other primates have established that the interhemispheric

transfer of white matter bundles is spatially organized in the corpus callosum to broadly reflect cortical neuroanatomy (Aboitiz, Scheibel, Fisher, & Zaidel, 1992; LaMantia & Rakic, 1990; Pandya & Seltzer, 1986). The macro organization of callosal connections promotes broad flexibility and efficiency of interhemispheric connections (Innocenti, Aggoun-Zouaoui, & Lehmann, 1995), and it has been proposed that the development of the corpus callosum in humans has enabled a more detailed pattern of hemispheric specialization and a more efficient use of intrahemispheric resources (Gazzaniga, 2000). An analysis of the callosum and its subregions may provide useful models of cortical development generally (Innocenti, 1994; Keshavan, Diwadkar, DeBellis, et al., 2002). By corollary, abnormalities in callosal connections may indicate more general impairments in corticocortical connections that may arise from altered neurodevelopment (Innocenti, Ansermet, & Parnas, 2003).

The corpus callosum has a rich developmental profile, maturing from early neonatal development well into the 3rd

Figure 19.1 Histological based topographic relationships between the corpus callosum sub-regions (shaded and hashed regions) and labeled regions of the neocortex (Witelson, 1989) are shown (a). Morphometric schemes that have been used by our group and others to sub-divided the corpus callosum in its midsagittal section show good correspondence with the known topographic mapping (b). Adapted from “Abnormalities of the Corpus Callosum in First Episode, Treatment Naive Schizophrenia,” by M. S. Keshavan, V. A. Diwadkar, K. Harenski, Rosenberg, et al., 2002, *Journal of Neurology, Neurosurgery, and Psychiatry*, 72(6), pp. 757–760.

decade of life. At birth, the corpus callosum is relatively iso-intense compared to other white matter, with its intensity in T_1 -weighted structural MRI images increasing rapidly within the first 8 months of postnatal development (Ballesteros, Hansen, & Soila, 1993; Georgy, Hesselink, & Jernigan, 1993). This increase in intensity is most likely related to profound changes in myelination and axonal development (Barkovich, 2000; Holland, Haas, Norman, Brant-Zawadzki, & Newton, 1986) and may relate to increased corticocortical and interhemispheric functional organization, particularly during childhood and adolescence (Giedd, 1999). Both cross-sectional and longitudinal studies have documented systematic structural growth during childhood and adolescence (DeBellis et al., 2001). Age-related correlations in cross-sectional samples (ages 4 to 18) are particularly notable in the splenium and isthmus (Rajapakse et al., 1996), and longitudinal studies in the same age range have confirmed systematic expansion of mid- and posterior callosal regions (Giedd, Blumenthal, Jeffries, Rajapakse, et al., 1999). Recent studies of callosal expansion have modified our understanding of the extent of the neurodevelopmental period as increases in callosal size have been reported up to the 4th decade of life (Pujol, Vendrell, Junque, Marti-Vilalta, & Capdevila, 1993), though the estimated rate of change, which is highest in childhood, decreases through adolescence and adulthood (Keshavan, Diwadkar, DeBellis, et al., 2002).

The known developmental profile of the corpus callosum in normative development has implications for neuropsychiatric illnesses and disorders. As alluded to earlier, many of these conditions are thought to be mediated by abnormal neurodevelopment at critical periods. In particular, vulnerability to Schizophrenia increases through adolescence, with the highest incidence coming in young adulthood. Abnormal callosal development may contribute to cortical disconnection, which is increasingly being seen as a core feature of the neurobiology of the illness (McGlashan & Hoffman, 2000). Furthermore, the critical neurodevelopmental period in psychiatric illness may extend beyond late adolescence and young adulthood, as initially thought. Recent neurobiological investigations have revealed developmental effects beyond adolescence (Bartzokis, 2002), findings that are relevant given that callosal development extends at least into the 4th decade of life (Pujol et al., 1993). Callosal development is also related to obstetric complications and environmental and cognitive influences, which are all associated with psychiatric disorders. For example, preterm children show marked abnormalities in callosal development (Stewart et al., 1999). Callosal width has been shown to be a function of literacy; illiterate subjects have thinner callosa

(Castro-Caldas et al., 1999). Callosal size has also been related to environmental and social effects. Monkeys reared in artificial and impoverished social environments show immature development of the corpus callosum compared to monkeys reared in more naturalistic and socially rich environments (Sanchez, Hearn, Do, Rilling, & HERNON, 1998). Such studies assume particular relevance in the context of illnesses such as Schizophrenia, mood disorders, and Autism, which may be associated with an aberrant pattern of neuroregulatory development as a result of abnormal social interaction during the critical stages of development. However, the modulatory role of development in the corpus callosum in psychiatric illness remains understudied.

Several assumptions regarding the corpus callosum and its role in information processing in mental illness have been made. Principal among them is the idea that interhemispheric connectivity in psychoses may be altered, either too much or, more likely, too little (David, 1994; Schrift, Bandla, Shah, & Taylor, 1986). Numerous psychological experiments and biological studies have been applied to answering these questions (Coger & Serafetinides, 1990). However, the evidence remains unclear, and it is not obvious how to reconcile findings from psychological experiments (in illnesses such as Schizophrenia) with the findings from MRI-based anatomical studies. Psychological studies on the integrity of the corpus callosum have used tasks that study patterns of the interhemispheric transfer of information.

The interhemispheric transfer of information has typically been studied using dichotic listening or split visual field paradigms. In these studies, information required for making judgments about stimuli is divided, with partial information being presented to each hemisphere of the brain; the information must then be integrated across hemispheres to facilitate a response (Baynes, Eliassen, Lutsep, & Gazzaniga, 1998). Alternatively, competing information is presented to each hemisphere, and it is presumed that interhemispheric integration results in response interference (David, 1993). Studies on facilitation have revealed decreased performance in Schizophrenia patients when information was presented to opposite visual hemifields or different hands (Carr, 1980; Craft, Willerman, & Bigler, 1987; Dimond, Scammell, Pryce, Huws, & Gray, 1979; Green, 1978). These results suggest that patients are impaired when required to make judgments based on the interhemispheric integration of information, therefore implying reduced callosal integrity. Studies on response inhibition using Stroop interference tasks have suggested an opposite pattern of interhemispheric transfer. In conditions in which the interhemispheric transfer of information would impede

performance, Schizophrenia patients performed worse than controls (David, 1993). The decrease in performance is attributed to increased response interference resulting from increased callosal information transfer. These results appear difficult to reconcile. However, recent experiments suggest a possible dichotomy in callosal transfer during conscious or automatic tasks. Patients may be particularly deficient when interhemispheric transfer must be done consciously, as in integration tasks, but may evince an opposite pattern during unconscious processing, such as during the interference tasks (Narr, Green, Capetillo-Cunliffe, Toga, & Zaidel, 2003).

Abnormal interhemispheric integration has also been associated with some of the core symptoms in Schizophrenia, specifically Schneiderian delusions (Nasrallah, 1985). The hypothesized mechanism for this is that a lack of appropriate integration may lead to a disinhibition of “awareness” between the two hemispheres, leading to a lack of unity of conscious experience. The result of this disinhibition may be an increase in positive symptoms such as delusions and thought insertions, which arise from the impaired brain’s inability to appropriately unify interhemispheric information into an undifferentiated percept. This theory is highly exploratory but is logically consistent with both the neuropsychological evidence and the phenotypic expressions of Schizophrenia.

CORPUS CALLOSUM AND NEUROPSYCHIATRIC ILLNESS

Perhaps the most informative studies on the callosum are those that use MRI to assess structure *in vivo*. We present a selective review of studies of callosal structure in three major areas of neuropsychiatric illness: Schizophrenia, mood disorders, and developmental disorders (with a focus on Autism). The neurodevelopmental bases of these disorders has either been widely established (e.g., Autism) or largely accepted as likely (e.g., Schizophrenia and mood disorders; Harrison, 2002; Lewis & Levitt, 2002). Further, all three may be associated with disturbances in the integrity of key neural networks within the cortex and between cortical and subcortical regions (Andreasen et al., 1999; Drevets et al., 1992; C. Frith, 2004). Impaired communication is suggestive of white matter pathology or impairment, making the corpus callosum an important candidate region for inquiry.

Schizophrenia

Schizophrenia is a particularly devastating mental illness marked by severe deficits in cognition and thought, disor-

dered thinking, and generally poor mental function. The illness is thought to be of polygenic origin and in part epigenetically expressed in abnormal neurodevelopment (Lewis & Levitt, 2002; Petronis, 2004). The widespread cognitive and thought impairments that are observed have led to the idea of Schizophrenia as an illness of disordered neurocircuitry or connectivity (Friston, 1999; Harrison, 1999; McGlashan & Hoffman, 2000; Selemon & Goldman-Rakic, 1999). Several abnormal pathways have been proposed, including the corticothalamic (Glantz & Lewis, 2000), corticothalamic-cerebellar (Andreasen, 1999), and corticocortical (Selemon & Goldman-Rakic, 1999). Recent studies have gone beyond looking at the loss of neuropil or decreases in the dendritic spine density of pyramidal neurons, and have shown extensive abnormalities in MRI-measured white matter integrity. The corpus callosum is a natural candidate for analyses of possible pathology.

The role of callosal abnormalities in Schizophrenia in particular and mental illness in general has been long suspected (B. Clarke, 1987), and several lines of work have provided experimental evidence of the relevance of its pathology in Schizophrenia. Whereas healthy brains are characterized by systematic asymmetric cortical organization in specific structures (Galuske, Schlote, Bratzke, & Singer, 2000), Schizophrenia is characterized by alterations in the normal patterns of structural and functional cerebral asymmetry (Crow, Colter, Frith, Johnstone, & Owens, 1989; Sommer, Ramsey, & Kahn, 2001). Patients show altered cerebral volumes and patterns of fMRI-measured activation during language tasks and decreases in right-handed preference (Delisi et al., 2002). The altered pattern of cerebral asymmetry is suggestive of altered interhemispheric pathways. More selective white matter imaging techniques have implicated disordered white matter connectivity in Schizophrenia, supporting the hypothesis of dysfunctional connectivity in the illness (Friston, 1999; Lim, Hedehus, et al., 1999; Lim & Helpert, 2002) and suggesting a role of callosal dysfunction in the illness. Investigations of callosal dysfunction in Schizophrenia have been based on neurobiological and behavioral approaches.

Studies on Callosal Tissue Integrity

Until recently, probing the integrity of neural tissue in psychiatric illness was restricted to the use of postmortem analyses of patient brains. The earliest study of postmortem chronic Schizophrenia patient brains suggested a thickening of the corpus callosum (Rosenthal & Bigelow, 1972), with subsequent reanalysis and remeasurement of the data indicating an increased effect in the anterior section of the structure, presumably encompassing the genu and the body (Bigelow, Nasrallah, & Rauscher, 1983).

However, negative studies have shown an absence of differences in axonal counts between patients and controls (Casanova et al., 1989). Generally consistent with these findings, it has been argued that Schizophrenia is characterized by unique myelinated interhemispheric pathways not observed in healthy control subjects, resulting in hyperconnective interhemispheric interaction (Randall, 1980) or by misconceptions between late-evolving brain regions such as the prefrontal and temporal cortices (Crow, 1998). More recent postmortem studies have identified selective reductions in axonal density across the subregions of the structure in the brains of female patients, suggesting subtle gender-related pathologies, with a decrease in the number of axons (Highley et al., 1999). These findings (although limited to female patients) are inconsistent with the hyperconnective idea, particularly in the genu (connecting the prefrontal cortex). Postmortem studies have suffered from the confounding of possible prolonged illness-related effects or medication effects on brain pathology; these problems are alleviated by *in vivo* MRI techniques.

MRI techniques are as yet imperfectly suited to assess *in vivo* tissue morphology; however, the selective application of structural and diffusion tensor imaging has proven informative. Signal intensities in T_1 -weighted images are general and nonspecific measures of tissue integrity and are sensitive to quantities of MR-visible water, which may in turn be revealing markers of tissue pathology (Diwadkar & Keshavan, 2002).

MRI signal intensity analyses have provided evidence of systematic changes in signal intensity with age across callosal substructures (Keshavan, Diwadkar, DeBellis, et al., 2002), plausibly associated with demonstrated changes in age-related myelination in the structure (S. Clarke et al., 1989). Analysis of callosal substructures in Schizophrenia showed significant decreases in signal intensity across most of the subregions—the genu, body, and isthmus (excluding the splenium)—suggesting an alteration in the integrity of white matter, possibly resulting from decreased myelination or microtubular density of callosal white matter (Diwadkar, DeBellis, Sweeney, Pettegrew, & Keshavan, 2004). These changes appear to be in part developmentally mediated. Age-related changes observed in controls are absent in patients, indicating that the continually developing profile of the structure may be arrested in individuals with the illness. Voxel-based analyses have provided evidence of statistical relationships between clinical symptoms and callosal white matter density. Reductions in white matter density have been documented in the genu of the corpus callosum (Hulshoff Pol et al., 2004), indicating possibly aberrant interhemispheric transfer between the frontal lobes. Significant negative correlations between reality distortion scores

measured from the Scale for the Assessment of Positive Symptoms (SAPS) subscales for hallucinations and delusions (Andreasen, 1984) and white matter density across the inferior surface of the corpus callosum have been reported, suggesting that increases in the magnitude of reality distortion are related to possible decreases in callosal integrity (Wright et al., 1995).

The nonspecificity of T_1 -weighted images can be overcome by the use of more specific techniques, such as diffusion tensor imaging (DTI; Rowley, Grant, & Roberts, 1999) or magnetization transfer imaging (MTI; van Buchem & Tofts, 2000). DTI is sensitive to the diffusion of water in the region of myelin sheaths, membranes, and white matter tracts. Neuropathology of white matter can result in changes in the patterns of anisotropic diffusion of water, leading to altered measurements of diffusion in DTI. Similarly, MTI depends on the transfer of magnetization between relatively mobile protons present in water, for example, and protons bound to macromolecules, fiber tracts, and myelin, and the transfer of magnetization is sensitive to changes in tissue integrity.

Both DTI and MTI are sensitive to age-related changes in white matter development, particularly in the corpus callosum (Sullivan & Pfefferbaum, 2003). Recent studies have documented age-related increases in fractional anisotropy (signifying better organization of white matter) in the genu and the splenium of the corpus callosum in neonates (Gilmore et al., 2004). Both techniques have been applied to the study of callosal integrity in Schizophrenia. A recent study examined changes in mean diffusivity (a general index of diffusion) and fractional anisotropy (an index of regional compared to global diffusion) in the genu and splenium of the corpus callosum. In the splenium, mean diffusivity was increased and fractional anisotropy decreased, suggesting impairments in the integrity of callosal tissue in those subregions (Foong et al., 2000). Subsequent support for these findings has been mixed. Adult studies have provided support for these findings in the splenium (Agartz, Andersson, & Skare, 2001), though few studies have attempted to examine diffusivity or anisotropy in callosal subregions (Ardekani, Nierenberg, Hoptman, Javitt, & Lim, 2003). At least one study in childhood-onset patients has been negative in both the genu and the splenium (Kumra et al., 2004).

Studies assessing altered patterns of symmetry provide another approach to study callosal dysfunction. For example, a normal pattern of greater leftward asymmetry in anisotropy values observed in the region of the genu in control subjects is reduced in Schizophrenia patients, suggesting possible reorganization of callosal fibers connecting the frontal hemispheres (Park et al., 2004). Recent work

has speculated that relative hyperconnectivity of callosal fibers in the anterior portion of the corpus callosum may be associated with the experience of auditory hallucinations. Fractional anisotropy values in the anterior aspects of the corpus callosum in patients experiencing frequent auditory hallucinations have been shown to be *greater* than in those experiencing infrequent hallucinators and even healthy controls (but see Rossell et al., 2001, for negative results in a similar study). This result is suggestive of greater white matter connectivity, which may result in spurious communications between brain regions, leading to the experience of auditory hallucinations (Gunther et al., 1991; Hubl et al., 2004). Similar positive relationships between positive symptoms (hallucinations and delusions) and callosal size have been demonstrated (Gunther et al., 1991).

Studies in Callosal Area and Shape

Studies in callosal shape follow a long tradition of morphometric investigations of neural structures in clinical neuroscience, and in particular Schizophrenia (Shenton et al., 2001). The assumption behind morphometry in clinical neuroscience is that microstructural abnormalities will express themselves as volumetric abnormalities in the structures of interest. With respect to the corpus callosum, most morphometric studies have been area-based rather than volumetric, partly as a result of difficulties in visualizing the lateral boundaries of this structure in midsagittal images of the brain (Bishop & Wahlsten, 1997).

Changes in callosal size in Schizophrenia have been investigated since the inception of high-resolution MRI in research. In a meta-analysis conducted approximately 10 years since the onset of the earliest work in this area, Woodruff and colleagues (Woodruff, McManus, & David, 1995) demonstrated that there was a decrease in callosal size in Schizophrenia of about 0.5 cm². Subsequent reviews have reiterated the findings of the earlier meta-analysis, demonstrating that a majority of studies document decreases in callosal area in Schizophrenia (Shenton et al., 2001). Problems of interpretation abound, though, as patient samples continue to differ in terms of age and primary diagnoses, and techniques for callosal measurement lack standardized validation. Statistical analyses of the data may or may not always correct for intracranial or total brain volume (Bishop & Wahlsten, 1997).

Some of our own recent work has indicated developmentally associated reductions in callosal area across the entire structure. Using a parcellation scheme from deLacoste and colleagues (1985), we conducted size and other image analyses of the genu, body, isthmus, and splenium in a sample of first-episode Schizophrenia patients ($n = 31$),

non-Schizophrenia psychotic controls, and healthy comparison subjects (Diwadkar et al., 2004; Keshavan, Diwadkar, Harenski, et al., 2002). Several striking results were observed. Area reductions specific to Schizophrenia patients were seen across all the subregions of the structure, confirmed by planned statistical contrasts. Further, these reductions appeared to be developmentally mediated: Significant age-related increases were observed in the size of substructures in healthy control subjects, but there was an absence of significant correlations in first-episode Schizophrenia patients. These results conform to the analyses of MRI signal intensity (see earlier discussion). In the sample of young first-episode patients in our studies (mean age = 24 years), reductions in callosal size were observed across all the principal subregions, suggesting a plausible decrease in the number or size of axonal fibers connecting the cortical hemispheres in Schizophrenia. Further, these reductions corroborated shape-based alterations of the callosum that had been previously documented in the same group of subjects (DeQuardo et al., 1999).

Our findings are broadly consistent with other MRI-based investigations of callosal size (Tibbo, Nopoulos, Arndt, & Andreasen, 1998), though negative results also exist (Meisenzahl et al., 1999). Investigations in first-episode patients with mild neuroleptic exposure have yielded similar results (Bachmann et al., 2003), with the additional finding of decreases being greater in men than in women. Studies have also demonstrated a positive relationship between callosal length and age of illness onset (Colombo, Bonfanti, & Scarone, 1994).

Investigations of callosal size abnormalities in the pre-morbid phase of Schizophrenia are lacking, and only limited studies exist in very early-onset patients. At least one study has documented callosal abnormalities in very young subjects showing symptoms of Schizophrenia or Schizotypal Personality Disorder. Compared to a group of age-matched controls, these patients showed a reduction in undifferentiated callosal area (Hendren et al., 1995). These findings are of importance because of the young age of the subject sampled (<12 years), which indicates a plausible callosal abnormality at very early stages of neurodevelopment. Other studies of young at-risk populations have been negative. Chua and colleagues (Chua, Sharma, Takei, Murray, & Woodruff, 2000) examined total and differentiated callosal size in a cohort of patients, their first-degree relatives, and healthy controls and were unable to replicate differences between patients and controls and correspondingly failed to document reductions in first-degree relatives. This negative result is perhaps important given the reasonable size of the sample ($n > 25$ in all groups), though the average age of the

samples exceeded 30, which may extend beyond the known developmental profile of the structure (Pujol et al., 1993). Some developmentally related analyses of callosal size have suggested altered profiles of maturation in childhood-onset Schizophrenia. In analyses of large samples (ages 8 to 24) of very young-onset patients, it appears that splenial size in this population appears to decline in late adolescence and young adulthood (compared to continuing increases in healthy controls; Keller et al., 2003; but see Jacobsen et al., 1997).

Collectively, the reviewed studies suggest a complex relationship between callosal integrity and Schizophrenia. The clarity of results has been confounded by differences in patient sample characteristics, in particular a dependence on study patients in the chronic phase and a relative absence of studies using neuroleptic-naïve first-episode subjects. The use of first-episode patients is particularly important as it avoids confounds of illness chronicity and effects of neuroleptic exposure and prolonged illness duration (Keshavan & Schooler, 1992). These are concerns given the demonstrated effect of antipsychotics on gray matter volume and the neurodegeneration observed following illness onset (Lieberman, 1999) and is an insurmountable limitation of most histopathological investigations. This may explain why the histopathological data have not been clearly confirmed by subsequent *in vivo* MRI investigations, and why studies on callosal morphometry have proven variable (Woodruff, Pearlson, Geer, Barta, & Chilcoat, 1993). Many important subgroups also remain understudied. For example, no *in vivo* studies of tissue integrity exist in young individuals at risk for Schizophrenia; therefore, knowledge of the development of the structure in the premorbid course of the illness is absent. It will be important to fill in these lacunae in knowledge to ascertain the relationship between abnormal neurodevelopment, callosal morphology, and Schizophrenia.

Other Psychiatric Disorders

It has been proposed that right hemisphere dysfunction is characteristic of depressive illness, and that interhemispheric communication may be disrupted. Studies using sleep electroencephalogram (EEG) have also shown low interhemispheric coherence in depressive patients (Armitage, 1995), suggesting callosal disconnectivity. Only one available study has examined the corpus callosum in unipolar depression and has found an increase in size (Wu et al., 1993). The corpus callosum appears to be larger in Bipolar Disorder as well (Hauser, Dauphinais, & Berrettini, 1989; Hauser et al., 1989).

Impaired interhemispheric connectivity has also been suggested in Obsessive-Compulsive Disorder (OCD; Mal-

let, Mazoyer, & Martinot, 1998). The corpus callosum appears to be bigger in OCD patients compared to controls (Farchione, Lorch, & Rosenberg, 2002; Rosenberg et al., 1997), contrasting with the reductions in this structure seen in Schizophrenia and Attention-Deficit/Hyperactivity Disorder (ADHD). The mean signal intensity is also altered in OCD patients, suggesting a possible increase in myelination. However, not all studies show corpus callosum changes in OCD (Kellner et al., 1991).

Severe early stress and maltreatment may produce a cascade of events that have the potential to alter brain development. Reduced area of the corpus callosum has been reported in both childhood Posttraumatic Stress Disorder (PTSD; DeBellis, Keshavan, et al., 1999) and in adults with this disorder (Villarreal et al., 2004). In the DeBellis study, subjects with PTSD did not show the normal age-related increases in the area of the total corpus callosum and its posterior region (splenium) compared to nonmaltreated subjects; however, this finding was more prominent in males with PTSD. Overall, callosal changes have been observed in a variety of psychiatric disorders, but the findings are not as consistent as in Schizophrenia. The small number of studies available and the variations in study populations limit conclusions that can be drawn.

Autism

Autism is a neurodevelopmental disorder characterized by abnormalities in social interaction and communication and by behavioral repetition or obsessive interest (Baron-Cohen, 2004). The syndrome is also typically accompanied by developmental delays in the onset of language. The phenotype of the syndrome is complex, and diagnosis is based on the presence of a subset of symptoms related to these impairments that by the age of 3 (Rapin, 1999). Autism is not a monolithic diagnosis; a complex subgroup Asperger's syndrome shares many of the core features but is characterized by an absence of delays in language, by an IQ in or above the average range, and by above-average abilities narrowly focused in limited domain(s). A specific characterization of the social deficits in cognition in Autism is the absence of a "theory of mind," or an inability to interpret correctly or attribute mental states to others (U. Frith, 1996), though this theory is narrow and excludes many of the secondary cognitive deficits, such as attentional and executive function impairments, that are also observed in the syndrome (U. Frith & Happé, 1994).

Because Autism presents itself early in development, it is thought of as fundamentally a developmental disorder, though its etiology remains generally obscure (Rapin &

Katzman, 1998). Heritability studies provide strong evidence of very high concordance rates in monozygotic twins (Bailey et al., 1995), suggesting a significant genetic component, and linkage studies are beginning to identify susceptibility genes (Lamb, Parr, Bailey, & Monaco, 2002). Like Schizophrenia, this syndrome may best be characterized as resulting from a complex interaction between genetic susceptibility and early environmental insults, leading to alterations in programmed neurodevelopment (Courchesne, Redcay, & Kennedy, 2004; Muhle, Trentacoste, & Rapin, 2004; Nicolson & Szatmari, 2003). The broad nature of cognitive deficits is suggestive of disconnection in the cortex or between cortical and subcortical circuits (Skoyles, 2002). Morphometric studies have also mapped out a diverse range of volumetric alterations in autistic individuals, including abnormal volumes of the cerebellum, subcortical structures (midbrain and brain stem), and total brain as well as parietal, temporal and frontal volumes (Brambilla et al., 2003). More focused structural MRI studies have provided plausible evidence of disordered connectivity between corticolimbic circuits in the form of reduced correlations in gray matter volume between key cortical and limbic regions (McAlonan et al., 2005). Functional MRI studies have hinted at disordered uni- and bilateral functional connectivity during language comprehension in Autism (Just, Cherkassky, Keller, & Minshew, 2004). Finally, recent evidence suggests an alteration in the pattern of cerebral asymmetry in Autism, with autistic subjects showing greater rightward structural asymmetry in an analysis of several cortical regions (Herbert et al., 2005). The combination of dysregulated early development and disconnections are suggestive of plausible corpus callosum pathology in Autism (Piven, 1997).

Studies on Callosal Tissue Integrity

The earliest study of *in vivo* tissue integrity in Autism using MRI signal intensity analysis suggested an absence of differences in MRI between controls and autistic subjects and a similar profile of intensity change as a function of age in both groups (Belmonte, Egaas, Townsend, & Courchesne, 1995). The authors suggested that these results indicated normal patterns of developmental myelination of the corpus callosum in Autism. On the other hand, recent voxel-based and DTI-based studies have provided evidence of positive findings, specifically reductions in white matter concentration and decreases in anisotropic diffusion.

In a sample of adolescent male autistics, significant reductions in white matter density were observed in the splenium of the corpus callosum (Waiter et al., 2005). More general reductions in the genu were observed in a sample of

16 high-functioning autistics (Chung, Dalton, Alexander, & Davidson, 2004). Few studies have applied DTI to the study of tissue integrity in Autism. Recent evidence indicates reduced anisotropy in the genu of the callosum (Barnea-Goraly et al., 2004). These studies (as in Schizophrenia) provide generally consistent evidence of abnormal tissue integrity in the corpus callosum in the Autism spectrum. The evidence from morphometric investigations of callosal size is similarly consistent.

Studies on Callosal Area

Discounting a few negative results showing an absence of changes in callosal area (Herbert et al., 2004), several studies of independent samples have documented robust changes in callosal size (Egaas, Courchesne, & Saitoh, 1995). Reductions in callosal area in both high-functioning and mentally retarded autistic patients have been reported (Manes et al., 1999), suggesting that deficits are not restricted to a particular IQ-based subgroup. Regional analyses have documented reductions in the area of the genu and the body of the structure as well (Hardan, Minshew, Harenski, & Keshavan, 2001; Piven, Bailey, Ranson, & Arndt, 1997).

Too few studies exist to discern a systematic regional pattern of callosal alteration in Autism. The pattern of evidence indicates both microstructural and morphometric changes, suggestive of a reduced integrity of the structure in the disorder.

Attention-Deficit/Hyperactivity Disorder

Interest in studying callosal impairment in ADHD stems from several observations. The corpus callosum contributes to attention by modulating resource allocation between the hemispheres and filtering interhemispheric signal transmission (Mikels & Reuter-Lorenz, 2004). ADHD has been thought to be associated with defects in interhemispheric communication (Magara, Ricceri, Wolfer, & Lipp, 2000). Furthermore, ADHD-like features are often seen in individuals with hypoplasia of the corpus callosum. Studies examining the corpus callosum in ADHD have generally shown reductions in the size of this structure (Giedd, Blumenthal, Molloy, & Castellanos, 2001; D. E. Hill et al., 2003), similar to reductions observed in Schizophrenia. Increased attentional problems have been associated with more prominent reductions in corpus callosal size (Kayl, Moore, Slopis, Jackson, & Leeds, 2000). ADHD patients also show a higher signal intensity ratio in the posterior regions in T_2 -weighted MRI, probably reflecting alterations in myelination (Pueyo et al., 2003).

Other Developmental Disorders

Callosal abnormalities have also been implicated in other developmental disorders, particularly those associated with risk for psychoses. For example, DiGeorge syndrome (also known as velocardial facial syndrome, or VCFS), caused by a specific deletion of chromosome 22q11, is associated with increased risk and rates of Schizophrenia and mood disorders, with studies showing an increased incidence rate of this deletion in Schizophrenia patients compared to healthy subjects (Usiskin et al., 1999). Investigations of callosal size in nonpsychotic children afflicted by the 22q11 deletion syndrome have shown abnormal increases compared to healthy controls (Shashi et al., 2004; Usiskin et al., 1999) in the body and the isthmus of the structure. Further, a relative lack of age-related changes in 22q11 samples has been observed. Reductions in total and regional callosal size have been reported in young individuals with Tourette's syndrome (Peterson et al., 1994), and Williams's syndrome (Schmitt, Eliez, Warsofsky, Bellugi, & Reiss, 2001; Tomaiuolo et al., 2002).

SUBSTANCE ABUSE AND CALLOSAL MORPHOLOGY

Substance abuse is widely associated with widespread teratogenic effects. Because the prenatal genesis and development of the corpus callosum begins to take place at around the same time as the greatest embryonic vulnerability to alcohol damage (Loeser & Alvord, 1968), it has been argued that the structure may embody the prenatal teratogenic defects due to maternal substance abuse and therefore a particularly crucial target for study (Bookstein, Sampson, Connor, & Streissguth, 2002; Johnson, Swayze, Sato, & Andreasen, 1996).

MRI-based investigations of brain morphology in chronic substance abusers and individuals prenatally exposed to high levels of cocaine and alcohol have documented widespread impairments in brain structure (Archibald et al., 2001; Roebuck, Mattson, & Riley, 1998; Sowell, Thompson, Mattson, et al., 2001) and cognitive function (Riley, McGee, & Sowell, 2004). Increases in impulsivity, suggesting a lack of prefrontal cortical-directed cognitive control (Moeller et al., 2005), and deficits in attention and visuospatial function have been documented (Sowell, Mattson, et al., 2001), along with reductions in prefrontal gray and white matter (Fein, Di Sclafani, Cardenas, et al., 2002; Fein, Di Sclafani, & Meyerhoff, 2002; O'Neill, Cardenas, & Meyerhoff, 2001). Midtemporal lobe structures such as the hippocam-

pus may also be particularly affected by adolescent alcohol abuse (DeBellis et al., 2000).

Significantly, substance abuse may have a critical developmental basis. Studies indicate a reduction in key electrophysiological components such as the P300 amplitude during visual and auditory processing (S. Y. Hill, Shen, Lowers, & Locke, 2000; S. Y. Hill & Steinhauer, 1993) in children at high risk for developing alcoholism. Further, studies of cocaine-dependent individuals have documented an absence of age-related expansion of frontal white matter, indicating plausibly reduced myelin expansion and, by inference, reduced functional connectivity of the neocortex (Bartzokis et al., 2002). The idea of reduced connectivity is supported by studies indicating an impairment in the interhemispheric transfer of information in children with heavy prenatal alcohol exposure (Roebuck, Mattson, & Riley, 2002) and in adults with chronic alcohol abuse (Schulte, Pfefferbaum, & Sullivan, 2004). Electrophysiological studies indicate reduced coherence of brain wave activity (reduced theta and gamma band coherence) among heavy drinkers compared to light drinkers (de Bruin et al., 2004), and resting state fMRI studies in cocaine abusers show reduced functional connectivity in the early visual system (Li et al., 2000). The widespread pattern of brain abnormalities, evidence of reduced cognitive function and connectivity, and patterns of developmental alterations in neurobiology suggest the corpus callosum as a target for impairment in substance abuse.

Midsagittal analyses of MRI images have helped elucidate many of the abnormalities associated with callosal morphology in children and adolescents suffering from neurotoxic effects of fetal alcohol exposure. These studies have suggested a higher rate of agenesis of the corpus callosum in children prenatally exposed to alcohol (Mattson, Schoenfeld, & Riley, 2001). Quantitative morphometric analyses have provided more evidence of callosal abnormalities: Reductions in callosal area of the genu and splenium in children with Fetal Alcohol Syndrome compared to controls have been reported (Riley et al., 1995). These more conventional morphometric analyses were extended using novel methods to detect changes in callosal shape, using landmark analyses (Bookstein, 1997) to assess changes in the shape of the structure as opposed to area. These studies have documented patterns of systematic displacement and increased variability of callosal shape in fetal alcohol-exposed subjects. In a study of adult males and females, Bookstein and colleagues (Bookstein, Sampson, Streissguth, & Connor, 2001) demonstrated that exposed individuals had increased variability in the shape of the callosum compared to controls. This pattern of

variability led to different patterns of differences between males and females. More significant variance for exposed males was observed under the isthmus (and, to some extent, the genu). For exposed females, the variance was primarily increased in the height of the callosal arch (i.e., the anterior and posterior divisions of the body), with some increases also observed in the ventral aspects of the isthmus and splenium. Similar shape analyses of callosal contouring have provided evidence of hyperdisplacement of the posterior aspects of the structure in exposed adolescents and young adults. In general, these studies suggest that the callosum is more inferiorly and anteriorly placed in exposed patients compared to controls (Sowell, Mattson, et al., 2001). These patterns were also related to the degree of alcohol exposure, providing evidence of a dose-related effect. Furthermore, studies have shown an increase in callosal white matter in patients with longer periods of sobriety, suggesting that the neurotoxic impact of substance abuse may not be irreversible (Pfefferbaum, Rosenbloom, Serventi, & Sullivan, 2002).

Recent examinations of callosal microstructure in substance abuse disorders also provide evidence of significant alterations. Chronic alcoholism is associated with reduced integrity of white matter in the genu of the corpus callosum (Pfefferbaum & Sullivan, 2002), and similar reductions have been documented in cocaine abusers (Moeller et al., 2005). These reductions have been related to impaired neurocognitive function, including increases in impulsivity and a reduction in the speed of interhemispheric processing, suggesting a neurobehavioral expression of such microstructural changes (Schulte, Sullivan, Muller-Oehring, Adalsteinsson, & Pfefferbaum, 2005). Recent studies suggest that these decreases may be associated with significant increase in intra- and extracellular fluid in callosal regions (Pfefferbaum & Sullivan, 2005), providing some evidence of the microstructural pathway for impairment in alcoholism.

The dramatic effects of substance abuse on callosal integrity indicate a pattern of structural vulnerability that includes both intrinsic factors (more likely to be associated with psychiatric conditions) and extrinsic factors, indicating reactivity to neurotoxic substances. The striking impairments that are observed in Fetal Alcohol Syndrome are of particular relevance in considering the role of experience-independent development on callosal development. As noted earlier, callosal development begins around approximately the 39th day postconception. This period is marked by the formation and differentiation of the commissural plate. Callosal fibers differentiate from the commissural

plate around the 75th postconception day, and adult-like morphology is achieved at around the 115th day (Loeser & Alvord, 1968). This pattern of prenatal development in the first trimester renders the corpus callosum particularly vulnerable to the toxic effects of ethanol, which are known to disrupt cell division, proliferation and migration, and the development of glia (Guerri, 1998). The relatively well-understood mechanisms of induced neurotoxicity in vitro in Fetal Alcohol Syndrome provide clear evidence of a neurodevelopmental lesion at a critical stage of callosal formation and development. The impact of this early lesion to the callosum on behavioral performance is profound, leading to severe mental and motor retardation in children exposed prenatally to alcohol or cocaine (Riley et al., 2004; Singer et al., 1997).

CONCLUSION AND FUTURE DIRECTIONS

As the major intercommissural pathway, the corpus callosum is an important white matter structure that is a natural target for investigation in neuropsychiatric illness. The developmental and topographic relationship with the neocortex further advances its importance as a region of interest. As reviewed here, the hyper- or hypoplasia of the corpus callosum is associated with a diverse variety of psychiatric illnesses and disorders. The findings are summarized in Table 19.1.

The precise mapping between in vivo MRI measurements of white matter volume or area and cellular processes such as

TABLE 19.1 Summary of Callosal Findings across Illnesses/Disorders

	Direction of Impairment	Regional Specifics	Developmental Effects
Schizophrenia	↓	Genu Body Splenium	Altered
Mood disorders	↑	N/A	N/A
Autism	↓	Genu Body Splenium	Altered
ADHD	↓	N/A	N/A
PTSD	↓	N/A	Altered
VCFS (22q11 deletion)	↑	Body Isthmus	Altered
OCD	↑	N/A	N/A

gliosis, myelination, or axonal integrity is not yet well understood. However, there are plausible justifications to correlate the observed *in vivo* findings to *ex vivo* or postmortem work in these illnesses.

In Schizophrenia, studies have suggested excessive gliosis in the corpus callosum in later-onset patients (Nasrallah, McCalley-Whitters, Bigelow, & Rauscher, 1983). In mood disorders, there is a suggestion of relative lack of subgenual prefrontal glia (potentially related to callosal morphology; Drevets, Ongur, & Price, 1998). None of the published work is specific to the corpus callosum, however, and to our knowledge, no histopathological data exist in developmental disorders such as Autism or in ADHD.

Accumulating studies have implicated myelin dysfunction as a principal neurobiological correlate of Schizophrenia (Davis et al., 2003), Bipolar Disorder (Tkachev et al., 2003), and developmental disorders such as Autism (Reiss, Feinstein, & Rosenbaum, 1986). In Schizophrenia, studies using MRI relaxometry have demonstrated plausibly lower myelin fraction, particularly in the genu of the structure (Flynn et al., 2003). Reduced myelination (expressed as reductions in myelin basic protein) in the limbic system of female bipolar patients has been reported, though no reports from the corpus callosum exist (Chambers & Perrone-Bizzozero, 2004). With recent explorations implicating myelin- and oligodendrocyte-related genes in the pathophysiology of both Bipolar Disorder and Schizophrenia (Tkachev et al., 2003), it is likely that reduced myelin in the corpus callosum may be associated with the reductions in callosal volume (Ogden et al., 2004). In Autism, evidence suggests that white matter abnormalities may stem from changes in oligodendrocytes and/or myelination; autistic children show a higher incidence of myelin basic protein antibodies, suggestive of altered myelination, and abnormalities in the expression of oligodendrocyte myelin glycoprotein, which may lead to impaired proliferation of oligodendrocytes or myelin (Dong & Greenough, 2004). Again, however, direct evidence linking such processes locally to the corpus callosum is lacking.

Axonal differences may also contribute to *in vivo* estimates of callosal abnormalities. In Schizophrenia, subtle differences in axonal density have been observed between patients and controls (Highley et al., 1999). Similar data in other disorders or syndromes are lacking, however.

An intriguing yet unresolved question is the potential relationship between impaired white matter and associated gray matter in psychiatric illness. Gray:white matter ratios are of importance in *in vivo* imaging for several reasons.

Segmentation procedures used to separate T_1 -weighted MRI images into gray, white, and cerebrospinal fluid components are subject to error from partial volume effects that limit the effectiveness of such techniques to absolutely quantitate either gray or white volume (Hohne & Pommert, 1996). Further, the balance of cortical gray and white matter is thought to be a metric of brain organization generally (Zhang & Sejnowski, 2000). Limited evidence in Schizophrenia suggests complementary reductions in gray and white matter in the heteromodal association cortices and the limbic lobe, suggesting convergent deficits in regional synaptic and axonal integrity, particularly in patients with negative symptoms (Sanfilipo et al., 2000; Sigmundsson et al., 2001). Alterations in gray:white brain ratio have been documented in adult and late-onset Schizophrenia patients as well (Bartzokis et al., 2003; Casanova & Lindzen, 2003). In general, given the high degree of interrelatedness in the developmental processes associated with synaptic proliferation and pruning and myelin and white matter development, it is reasonable to assume that callosal abnormalities are related to complementary gray matter impairments. Indeed (at least in Schizophrenia), gray matter reductions have been documented in the regions that impaired callosal areas connect (Shenton et al., 2001).

Direct evidence that speaks to developmental trajectories in callosal change in illnesses and disorders is relatively sparse. As noted earlier, a few studies have demonstrated alternative pathways of callosal change in cross-sectional Schizophrenia samples compared to healthy controls (Keshavan, Diwadkar, Harenski, et al., 2002), though similar data in other illnesses and disorders are lacking. More thorough analyses of age-related callosal changes in different disorders may be compelling for several reasons. Illnesses such as Schizophrenia and Bipolar Disorder and disorders such as Autism are illnesses of neurodevelopment. In fact, several genes implicated in their pathophysiology are the genes that are thought to be involved in neurodevelopment as well (Jones & Murray, 1991; Muhle et al., 2004). Furthermore, changes in expression of myelin-encoding genes have been documented in Schizophrenia and Bipolar Disorder (Aston, Jiang, & Sokolov, 2005; Tkachev et al., 2003). From such studies we can extrapolate that the relative phenotypic distinctions between Schizophrenia and Bipolar Disorder emerge as a result of different neurodevelopmental expressions at different time points (J. Walker, Curtis, Shaw, & Murray, 2002). As our own work has recently established, different patterns of change in MRI-measured callosal morphology are observed in childhood, adolescence, and young adulthood (Keshavan, Diwadkar, DeBellis, et al., 2002).

Given the emerging consensus that derailed neurodevelopment is a mechanism that may underlie psychiatric illness in general (Kreipke, Rosenberg, & Keshavan, 2004), comparative studies in at-risk psychiatric populations may provide information on specific time points at which derailment of callosal development occurs. The timing and the extent of such derailment may provide important insights on the future emergence of phenotypically nonoverlapping psychiatric diagnoses such as Schizophrenia and Bipolar Disorder (J. Walker, Curtis, & Murray, 2002) and may elucidate the developmental course of syndromes such as Autism (McAloon et al., 2005) and ADHD (Giedd et al., 2001).

The corpus callosum's unique spatial relationship with cortical regions provides opportunities to estimate the patterns of derailed neurocircuitry in development. Different patterns of change in callosum regions may be associated with different clinical phenotypes and may implicate overlapping or nonoverlapping circuits in the brain. As an example, although the effect of alterations in callosal morphology in an illness such as Schizophrenia is largest in the genu (which connects the prefrontal cortices), alterations are observed across all subregions, consistent with the idea of the illness being a more generalized disconnection syndrome of the brain. Detailed analyses of this nature in other disorders may help clarify the nature and the degree of estimated disconnection.

A general framework with which to understand the nature and the directionality of callosal alterations in diverse syndromes remains elusive. The understanding of abnormal neurobiology in many of these syndromes is continually evolving, but at present, there is no plausible single unitary mechanism or set of mechanisms that may explain callosal abnormalities. One candidate mechanism may be stress or trauma to the brain that impacts at critical stages of development (DeBellis, Baum, et al., 1999; Teicher, Andersen, Polcari, Anderson, & Navalta, 2002; Teicher et al., 2003), leading to axonal damage in critical cortical and callosal regions.

Increasingly, childhood stress and abuse have been associated with abnormal development of the brain in general and the corpus callosum in particular. In an early study, Teicher and colleagues (1997) demonstrated significant reductions in the size of the body of the corpus callosum in young patients with a history of childhood abuse. These patients also demonstrated an abnormal pattern of EEG-measured inter- and intrahemispheric coherence of brain activation, suggesting that abuse may have altered the normative pattern of brain development (Ito, Teicher, Glod, & Ackerman, 1998). Recent studies have extended this work to indicate callosal abnormalities not only in abused but in neglected children as well (Teicher et al., 2004). These

MRI-measured reductions in humans are consistent with experimental studies documenting profound effects of rearing and isolation on the corpus callosum in the rhesus monkey (Sanchez et al., 1998) and suggest that early stress through trauma or neglect to compacted white matter structures like the corpus callosum may derail or reverse the known patterns of myelination in that structure (McGraw, Liang, & Provenzale, 2002). The cascading effects of alterations in the stress-response system may lead to reverberating effects throughout development. For example, prolonged stress is known to impair the development of the glucocorticoid receptors, eventually leading to enhanced noradrenergic, corticosteroid, and vasopressin responses to stress (Teicher et al., 2002). Consistent with this, experimental studies have demonstrated that early glucocorticoid administration interferes with glial cell division and myelination (Lauder, 1983).

Psychosocial stress is implicated as a precipitating factor in several mental illnesses, including Schizophrenia. In particular, the biological effects of stress are modulated by the hypothalamic-pituitary-adrenal axis, which is known to function abnormally in the illness (Corcoran et al., 2003), and may impact normal development in Schizophrenia (E. F. Walker, Diforio, & Baum, 1999). It is likely that certain stressors may severely compromise the stress hormone response and may lead to unpredictable and myriad effects on neural differentiation and myelination, leading to hypodevelopment of the corpus callosum (and other structures) in a number of psychiatric disorders, such as Schizophrenia and Bipolar Disorder, and environmental insults, including drug abuse and Fetal Alcohol Syndrome. Thus, the pathways to callosal impairment may be diverse in origin but may converge on a similar end point.

The effects of stress and neurotoxicity are not specific to the corpus callosum. For example, malfunctions of the glutamate system leading to neurotoxic-related neuronal loss and abnormal neuron development have been generally implicated in Schizophrenia (Konradi & Heckers, 2003) and may impact several regions of the brain. Genetic factors may also play a critical role in abnormal callosal morphology. Recent studies have identified displacements of the corpus callosum in unaffected monozygotic twins of Schizophrenia patients, suggesting a heritable component to callosal morphology (Narr et al., 2002). Studies in healthy monozygotic and dizygotic twin populations and elderly populations have also confirmed a heritable basis to callosal morphology, with a large proportion of variance in structure size accounted for by genetic factors (Pfefferbaum, Sullivan, & Carmelli, 2004; Scamvougeras, Kigar, Jones, Weinberger, & Witelson, 2003).

Emerging MRI techniques may contribute to increased understanding of the specific abnormalities of in vivo microstructure of the corpus callosum. For instance, fiber pathway abnormalities may be the endophenotype of interest, but conventional MRI is not informative of such deficits. White matter imaging techniques such as DTI and MTI may provide more focused answers, though they are also limited by the underlying topography of fiber pathways. Magnetic resonance spectroscopy techniques, especially with the use of high-field magnets (3 Tesla or higher), can quantify changes in in vivo neurochemical markers such as glutamine and glutamate that are integral to glial and neuronal interactions.

Psychiatric illness and disorder may render some brain regions more generally vulnerable than others. The corpus callosum occupies a unique place in the taxonomy of regions, and it is not surprising that it is weakly or strongly implicated in a variety of disorders. Key directions for the future are to understand the specific timing (in terms of developmental stage) when callosal impairments begin to be manifest and the relationship between such impairments and neuropsychological function. Longitudinal studies that employ multimodal imaging techniques (fMRI, DTI, etc.) in conjunction with focused tasks (e.g., split-hemispheric integration tasks) may provide answers about the progression and the nature of callosal impairments. The role of white matter in psychiatric illnesses and conditions is becoming better elucidated (Kumar & Cook, 2002). Therefore, studies of the corpus callosum may play a key role in revealing important aspects of the developmental pathophysiology of psychiatric illnesses and disorders.

The personality disorders, as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*; American Psychiatric Association [APA], 1994), are thought to represent stable, enduring, and consistent maladaptive personality configurations that result in considerable occupational and social impairment as well as subjective distress for many who suffer from them. However, relatively little is known about what causes personality disorders to develop or how they are maintained to varying degrees over time. Although the 1980s saw an upsurge in interest in the definition and assessment of personality pathology, it is fair to say that even 20 years later, many questions remain as to the proper classification architecture for personality pathology, the nature of the relationship between normal personality and temperament processes and personality pathology, and the life span trajectories for those who are afflicted with personality pathology (Lenzenweger & Clarkin, 2005). In short, the cause of personality pathology remains essentially unknown.

Before tackling the substantive focus of this chapter, which is to provide a provisional sketch for aspects of a developmental psychopathology for personality disorders, we would like to mention two “big facts” regarding personality disorders as presently conceived. These big facts, as it were, have impacted our thinking and provided the impetus, in part, for many of the ideas developed here, and they have implications for the developmental psychopathology approach. Although long thought to be relatively prevalent based on impressions from practitioners in office and clinic settings, only recently have quality prevalence estimates emerged for personality pathology in the nonclinical and general population. Lenzenweger, Loranger, Korfine, and Neff (1997) provided the first empirical prevalence estimate for personality pathology derived from a nonclinical sample and employing experienced diagnosticians. These investigators reported a prevalence of 11% for “any personality disorder” (Lenzenweger et al., 1997), a rate that was replicated in subsequent studies by Torgersen, Kringlen, and Cramer (2001; 13%), Samuels et al. (2002; 9%), and Grant et al. (2004; 14.8%). Thus, although there is considerable debate about the proper way to define personality pathology,

This work was supported by National Institute of Mental Health research grants MH-55347 awarded to R. A. Depue and MH-45448 awarded to M. F. Lenzenweger.

it is safe to say that there is a rate of impairing psychopathology in the general population that is nontrivial. In fact, it appears that somewhere between 1 in 7 and 1 in 10 adults in the population is likely to suffer from a diagnosable personality disorder. This is clearly a problem of considerable proportion, worthy of both clinical and scientific interest. This rate of psychopathology suggests that the developmental determinants of personality pathology are not likely to be rare. Moreover, as with any complex phenotype, we anticipate that multiple lines of influence will interact to create what is known as a personality disorder; thus, one should not expect to find simple, causal explanations for the development of these forms of psychopathology (e.g., personality disorder develops solely from severe childhood sexual abuse).

A second big fact concerns the manner in which personality disorders are actually defined in terms of their basic nature, specifically their putative stability over time. The current diagnostic nomenclature (*DSM-IV*, APA, 1994) and its immediate predecessors (*DSM-III*, APA, 1980; *DSM-III-R*, APA, 1987) all defined personality disorders as “enduring patterns” of behavior that are “inflexible” and “stable over time.” Clearly, the picture that the *DSM* model has painted is one of considerable temporal stability for personality pathology; however, it is noteworthy that these descriptions of stability in the APA nomenclature were *never* based on empirical data. At the time the *DSM-III* was published, there were no empirical data available from prospective, multiwave longitudinal studies on which such assertions could be based. The basis for the *DSM* position on the temporal stability of the personality disorders came largely from the impressions of practitioners, long held beliefs about the basic nature of personality pathology, and a small number of test-retest studies. The test-retest studies, though useful for the establishment of psychometric characteristics for assessment instruments, provided little to no insight into the question of long-term stability of the personality disorders owing to the well-known limitations and artifacts inherent in the test-retest study design. The first major longitudinal study in this area that met contemporary design criteria, known as the Longitudinal Study of Personality Disorders (LSPD; Lenzenweger, 1999; Lenzenweger et al., 1997; Lenzenweger, Johnson, & Willett, 2004), was only begun in 1990. Other longitudinal studies of the personality disorders were begun later (e.g., Gunderson et al., 2000; J. G. Johnson et al., 2000; Shea et al., 2002; Zanarini, Frankenburg, Hennen, & Silk, 2003). With the passage of nearly 10 years, during which the various longitudinal studies have been under way, a clear pattern has begun to emerge re-

garding the stability of personality pathology over time. Despite one or another methodological artifacts, all of the existing longitudinal studies show consistent and compelling evidence of mean level decreases in personality disorder features over time (J. G. Johnson et al., 2000; Lenzenweger, 1999; Lenzenweger, Johnson, et al., 2004; Shea et al., 2002; Zanarini et al., 2003). Data from the LSPD revealed mean level change in personality disorder features over time (Lenzenweger, 1999), and more recent analyses of the LSPD data, using the more sensitive approach of individual growth curve analysis, revealed a decline of 1.4 personality disorder features per year (Lenzenweger, Johnson, et al., 2004). Such change represented a “medium” effect size (Rosenthal & Rosnow, 1991). It is important to note that the change observed in the LSPD subjects was not accounted for by other comorbid mental disorders (e.g., unipolar depression, anxiety disorders, substance abuse) or exposure to conventional psychiatric treatments. With respect to the other longitudinal efforts, in a study limited to Borderline Personality Disorder (BPD), Zanarini et al. found massive declines in symptoms, such that 73.5% of previously diagnosed BPD subjects were remitted at 6-year follow-up, suggesting nontrivial mean level changes in BPD symptoms. J. G. Johnson et al. found 28% to 48% reductions in personality disorder features with time in a study based on careful chart reviews of the same people over time. Shea et al. found 66% of the participants in a longitudinal study of diagnosed personality disorder patients dropped below diagnostic thresholds in 1 year, with highly significant (revealing substantial effects) declines for continuously measured personality disorder symptoms. The Shea et al. data are somewhat difficult to interpret, as the assessors of the patients were not blind to previous assessments and all of the patients in the study were also in treatment during the course of the study. Nonetheless, the assumption of stability of the personality disorders over time, despite being widely espoused as well as included in the formal diagnostic nomenclature, is eroding in the face of empirical data.

Thus, from the standpoint of developmental psychopathology, the personality disorders represent a domain of psychopathology that actually shows clear evidence of change over time, although the precise determinants of such change remain to be specified. Moreover, such change also suggests that the phenomena known as personality disorders are best thought of as plastic or dynamic constructs that can show flexibility with the passage of time. Any developmental psychopathology account of the emergence and development of such disorders must take into account

this plastic and dynamic nature. Finally, regarding the long-term developmental picture of the personality disorders, it is fair to say that, as a field, we still have no idea, from properly designed multiwave studies, what the exact nature of personality disorder stability and change is over the life span.

The developmental psychopathology perspective (Cicchetti & Cohen, 1995; Rutter, 1997, 2000; see also Lenzenweger & Haugaard, 1996) seeks to illuminate the interaction between normative and abnormal development. The study of personality disorders from a developmental psychopathology perspective strikes us as having considerable potential. In our theoretical work on the neurobehavioral underpinnings of personality disorders, we have sought to integrate what is known about normal personality and temperament systems with what is known about the most common personality disorder phenotypes. Moreover, personality pathology, by its very definition, calls out to be studied from a longitudinal perspective and thus should be properly studied using methods, measures, and time frames that will help to illuminate change and development across the life span. Within this life span developmental perspective, which can be developed only in preliminary form here, we can well imagine that there are not only risk factors that can facilitate the emergence of personality disorders (both within the person and in the environment), but that there are also protective factors that mitigate against the emergence of a personality disorder. Clearly, whether or not one develops a personality disorder depends on a number of contingencies, and the pathway that runs from such risks and underlying liabilities to a disordered personality organization is not one that is fixed in granite. Rather, we envision a relatively complex, interactive dance taking place between neurobehavioral systems, brain development, and environmental inputs that can result, but may not necessarily result, in recognizable personality pathology. In this context, we note the importance of *multiple levels of analysis* (Cicchetti & Dawson, 2002; Kosslyn & Rosenberg, 2001) in the conceptualization of personality pathology. A multiple-levels-of-analysis approach represents a research and theoretical vantage point that seeks to understand and model complex psychological processes and constructs at levels ranging from the cellular to the interpersonal and social. Ideally, models of complex phenomena, such as personality pathology, should seek to simultaneously consider factors within the person (e.g., neurobiology, neural circuitry), at the level of the person (e.g., individual differences), and between persons (e.g., interpersonal, social functioning). We endorse this valuable research perspec-

tive, and the model we present seeks to understand personality pathology across multiple levels of analysis.

In our chapter, we sketch out what we believe to be the foundational elements of personality pathology; however, we emphasize that the interaction of these elements likely continues across time and that even in the case of personality disordered individuals, it is likely that their disorder, as it were, continues to exert some influence on psychological development and functioning over time. In summary, in our view of the development of what we term “personality disturbance,” such disturbance is the product of a matrix of highly interactive systems of neurobehavioral processes. This matrix, of course, interacts with the environment through time and across contexts, including developmental transitions, to allow for the emergence of personality pathology.

THE PROBLEM OF MODELING NONENTITIES

From a scientific perspective, it is really no longer possible to accept the notion that personality disorders (PDs) represent distinct, categorical diagnostic entities. The behavioral features of PDs are not organized into discrete diagnostic entities, and multivariate studies of behavioral criteria fail to identify factors that resemble existing diagnostic constructs (Block, 2001; Ekselius, Lindstrom, von Knorring, Bodlund, & Kullgren, 1994; Livesley, 2001; Livesley, Schroeder, Jackson, & Jang, 1994). Indeed, just the opposite is observed: The behavioral features of PDs merge imperceptibly in a continuous fashion across diagnostic categories, resulting in (1) significant overlap of behavioral features across categories and hence diagnostic comorbidity within individuals and (2) symptom heterogeneity within categories and hence frequent (and most common in some studies) application of the ambiguous diagnosis of Personality Disorder Not Otherwise Specified (Livesley, 2001; Saulsman & Page, 2004). Moreover, aside from schizotypy/schizotypic disorders, the existing latent class and taxometric analysis literature on PDs generally does *not* provide support for distinct entities in the PD realm in any compelling fashion, and some provisional taxonomic findings for Borderline and Antisocial PDs are open to doubt. It is, accordingly, not surprising that diagnostic membership is not significantly associated with predictive validity as to prognosis or psychological or pharmacological treatments (Livesley, 2001). Such a state of affair recently led Livesley to declare that “evidence on these

points has accumulated to the point that it can no longer be ignored” (p. 278).

Such a state of affairs supports proponents of a dimensional approach to PDs, who note that (1) the behavioral features of PDs not only overlap diagnostic categories, but also merge imperceptibly with normality (Livesley, 2001; Saulsman & Page, 2004); and (2) the factorial structure of behavioral traits associated with PDs is similar in clinical and nonclinical samples (Livesley, Jackson, & Schroeder, 1992; Reynolds & Clark, 2001). Furthermore, the higher-order structure of PD traits resembles four of the five major traits identified in the higher-order structure of normal personality (Clark & Livesley, 1994; Clark, Livesley, Schroeder, & Irish, 1996; Reynolds & Clark, 2001). These findings suggest that PDs may be better understood as emerging at the extremes of personality dimensions that define the structure of behavior in the normal population (for reviews of this position, see P. T. Costa & Widiger, 1994; Depue & Lenzenweger, 2001; Lenzenweger & Clarkin, 1996; Livesley, 2001; Reynolds & Clark, 2001; Saulsman & Page, 2004; Widiger, Trull, Clarkin, Sander-son, & Costa, 1994).

This realization has led to innumerable attempts to illustrate the association of personality traits to PD diagnostic categories. Most of these studies have relied on the so-called five-factor model of personality, which defines a structure characterized by the five higher-order traits of extraversion, neuroticism, agreeableness, conscientiousness, and openness to experience. Although Reynolds and Clark (2001) demonstrated that four of these traits (openness shows no consistent relation to PDs; Saulsman & Page, 2004) account for a substantial proportion of the variance in interview-based ratings of *DSM-IV* PD diagnoses, a recent meta-analysis of similar studies demonstrated the limitation of the approach of correlating four traits with PDs (Saulsman & Page, 2004). The meta-analysis showed that most such studies illustrate the following problems: (1) The correlation of these four traits with PD categories is moderate to weak; (2) the complex “entity” of a PD category is defined by as little as one trait but never by four traits in a significant way; and (3) single traits (e.g., neuroticism) characterize more than one, and sometimes several, putatively distinct PDs. For example, how helpful is it to know that Histrionic PD is characterized by moderately high extraversion but by no other trait; or, similarly, that Dependent PD is associated with moderately high neuroticism but by no other trait? To what line of research or clinical intervention does that knowledge lead? Moreover, the traits relate more highly to PD categories that are studied in non-clinical samples, indicating that the traits may be less valu-

able in defining clinical entities. What the meta-analysis did reveal is that most PDs manifest, in common, higher trait levels of neuroticism and lower trait levels of agreeableness, meaning that most individuals with PDs are subject to negative emotionality and impaired affiliative or interpersonal behavior. Thus, again, when PD categories serve as the outcome variable, personality traits provide little in the way of power to discriminate between such categories. Overall, then, it is probably not unfair to conclude that such correlational studies have done little to inform the issue of continuity from personality systems to states of disorder, most of them having merely specified correlates of PDs and nothing more, and most of these studies lacked an underlying framework for understanding both personality and PDs.

The paradox in all of this is that, despite knowing that the PD diagnostic categories are unreliable and lack compelling construct and predictive validity, researchers cling to the approach of relating major personality traits, typically considered at the conceptual level of analysis one trait at a time, to *nonentities* of PDs. How can one learn something substantive by relating four higher-order traits to heterogeneous behavioral phenomena that are clustered conceptually (not statistically or theoretically) into diagnostic entities? As Livesley (2001) aptly notes, because PD diagnoses are so fundamentally flawed, it is not important to know whether each PD diagnosis can be accommodated by a dimensional model. Furthermore, the problem in this approach does not appear to be explained simply by use of a small number of broad traits. When the 30 facet scales of the NEO-PI (Personality Inventory) were correlated with PD categories, only modest gains were achieved relative to the use of the four major traits (mean difference in $R^2 \sim 0.04$; Dyce & O’Connor, 1998; Millon, 1997).

Perhaps one of the most crucial issues associated with a dimensional personality approach to PDs is that the substantive meaning of the four major traits is not clear and generally has been a neglected topic (Block, 2001). Put differently, there is not a clear understanding as to which underlying neurobehavioral systems these traits reflect, which the behavioral genetic literature implies they must (Tellegen et al., 1988). Accordingly, in this chapter, we promote an alternative empirical and theoretical approach to PDs. First, we embrace the fact that PDs do not exist as *distinct entities*; therefore, we refer to the behavioral manifestations that emerge at the extremes of personality dimensions as *personality disturbance* rather than disorder. We exclude Schizotypal and Paranoid Personality Disorders from our model, because there is evidence that they may be genetically related to Schizophrenia (e.g., Kendler

et al., 1993; Lenzenweger & Loranger, 1989), representing an alternative manifestation of Schizophrenia liability (Lenzenweger, 1998), and studies of the latent class structure of schizotypy show evidence that its underlying nature is more likely of a taxonic or qualitative nature (Korfine & Lenzenweger, 1995; Lenzenweger & Korfine, 1992). The term *disorder*, though less formal and regimented than the term *disease*, nevertheless connotes a relatively coherent symptomatic entity that, with more empirical attention, will be characterized by distinct boundaries and underlying dysfunction. We do not believe that, as PDs are currently conceived, such a state of scientific credibility will be achieved and hence warrant the use of the terms syndrome, disorder, or disease. Second, we attempt to delineate the nature of the neurobehavioral systems that we postulate underlie the four major traits of personality. In so doing, we hope to provide a substantive meaning to the four major personality traits that supersedes the extant variation in trait labels and psychological concepts.

The implications of defining personality traits in terms of neurobehavioral systems leads to a third part of the chapter, where we derive a model of personality disturbance based on the *interaction* of these neurobehavioral systems. Though genetically speaking, it may be possible to conceive of the neurobiological variables associated with neurobehavioral systems as subject to independent influences, it is impossible to imagine that neurobehavioral systems are independent at a functional level. Similarly, it is impossible to imagine that personality traits can be associated in an independent manner to PDs. Neurobehavioral systems, and the personality traits that reflect their influence, interact to produce complex behavior patterns—personality as a whole—in a multivariate fashion. Therefore, our model of personality disturbance rests on a foundation of multivariate interaction of neurobehavioral systems. Such an interaction may yield a phenotypic clustering of behavioral signs or symptoms that could be taken to suggest a demarcation, perhaps indicative of latent threshold effects in the neurobehavioral systems, but the observed clustering represents the end product of underlying continuous dimensional neurobehavioral systems. Furthermore, although it is true that our model is dimensional in nature, where personality disturbance lies at the extreme of normal, interacting personality dimensions, it is worth noting that no assumption is made herein that phenotypic dimensions of personality are genetically continuous. The phenotypic continuity could well represent several underlying, *distinct* genotypic distributions (Gottesman, 1997), as may be the case even within the

normal range of variation of some personality traits (Benjamin et al., 1996; Ebstein et al., 1996).

NEUROBEHAVIORAL SYSTEMS UNDERLYING HIGHER-ORDER PERSONALITY TRAITS

The higher-order structure of personality converges on three to seven factors that account for the phenotypic variation in behavior (Digman, 1997; Tellegen & Waller, in press). Although there is considerable agreement on the robustness of at least four higher-order traits, there is nevertheless substantial variation in the definition of these traits because researchers emphasize different characteristics depending on their trait concepts. Our model focuses on four higher-order traits that are robustly identified in the psychometric literature and that we define with reference to coherent neurobehavioral systems. Higher-order traits resembling *extraversion* and *neuroticism* (anxiety) are identified in virtually every taxonomy of personality. Affiliation, termed *agreeableness* (P. Costa & McCrae, 1992; Goldberg & Rosolack, 1994) or *social closeness* (Tellegen & Waller, in press), has emerged more recently as a robust trait and comprises affiliative tendencies, cooperativeness, and feelings of warmth and affection (Depue & Morrone-Strupinsky, in press). Finally, some form of impulsivity, more recently termed *constraint* (Tellegen & Waller, in press) or *conscientiousness* (due to an emphasis on the unreliability, unorderliness, and disorganization accompanying an impulsive disposition; P. Costa & McCrae, 1992; Goldberg & Rosolack, 1994), frequently emerges in factor studies.

Agentic Extraversion and Affiliation

Agentic extraversion and affiliation represent well established neurobehavioral systems. Modeling these systems entails consideration of both the complexities of interpersonal behavior as well as the relations between the two systems.

Trait Complexities Related to Interpersonal Behavior

Interpersonal behavior is not a unitary characteristic, but has two major components. One component, *affiliation*, reflects enjoying and valuing close interpersonal bonds and being warm and affectionate; the other component, *agency*, reflects social dominance, assertiveness, exhibitionism, and a subjective sense of potency in accomplishing goals. These two components are consistent with the two inde-

pendent major traits identified in the theory of interpersonal behavior: warm-agreeable versus assured-dominant (Wiggins, 1991). Recent studies have consistently supported a two-component structure of interpersonal behavior in joint factor analyses of multidimensional personality questionnaires (Church, 1994; Church & Burke, 1994; Digman, 1997; Morrone-Strupinsky, Depue, Scherer, & White, 2000; Morrone-Strupinsky & Depue, 2004; Tellegen & Waller, in press), where two general traits were identified in each case as affiliation and agency (Depue & Collins, 1999). Lower-order traits of social dominance, achievement, endurance, persistence, efficacy, activity, and energy all loaded much more strongly on agency than on affiliation, whereas traits of sociability, warmth, and agreeableness showed a reverse pattern. Such findings have led trait psychologists to propose that affiliation and agency represent distinct dispositions (Depue & Collins, 1999; Depue & Morrone-Strupinsky, in press; Tellegen & Waller, in press): Whereas affiliation is clearly interpersonal in nature, agency represents a more general disposition that is manifest in a range of achievement-related, as well as interpersonal, contexts (P. Costa & McCrae, 1992; Goldberg & Rosolack, 1994; Tellegen & Waller, in press; Watson & Clark, 1997; Wiggins, 1991).

Association of Agentic Extraversion and Affiliation with Two Neurobehavioral Systems

Behavioral systems may be understood as behavior patterns that evolved to adapt to stimuli critical for survival and species preservation (Gray, 1973, 1992; MacLean, 1986; Schneirla, 1959). As opposed to specific behavioral systems that guide interaction with very specific stimulus contexts, *general* behavioral systems are more flexible and have less immediate objectives and more variable topographies (Blackburn et al., 1989; MacLean, 1986). General systems are activated by broad *classes* of stimulus (Depue & Collins, 1999; Gray, 1973, 1992) and regulate general emotional-behavioral dispositions, such as desire-approach, fear-inhibition, and affiliative tendencies, that modulate goal-directed activity. It is the general systems that directly influence the structure of mammalian behavior at higher-order levels of organization, because, like higher-order personality traits, their pervasive modulatory effects on behavior derive from frequent activation by broad stimulus classes. *Thus, the higher-order traits of personality, which are general and few, most likely reflect the activity of the few, general neurobehavioral systems.*

We have suggested that the two traits of agentic extraversion and affiliation reflect the activity of two neurobe-

havioral systems involved in guiding behavior to *rewarding* goals (Depue & Collins, 1999; Depue & Morrone-Strupinsky, in press). Reward involves several dynamically interacting neurobehavioral processes occurring across two phases of goal acquisition: appetitive and consummatory. Although both phases are elicited by unconditioned incentive (reward-connoting) stimuli, their temporal onset, behavioral manifestations, and putative neural systems differ (Berridge, 1999; Blackburn et al., 1989; Depue & Collins, 1999; Di Chiara & North, 1992; Wyvell & Berridge, 2000) and are dissociated in factor-analytic studies based on behavioral characteristics of animals (Pfaus, Smith, & Cooper-Smith, 1999).

An appetitive, preparatory phase of goal acquisition represents the first step toward attaining biologically important goals (Blackburn et al., 1989; Hilliard, Domjan, Nguyen, & Cusato, 1998). It is based on a mammalian behavioral system that is activated by, and serves to bring an animal in contact with, unconditioned and conditioned rewarding incentive stimuli (Depue & Collins, 1999; Gray, 1973; Schneirla, 1959). This system is consistently described in all animals across phylogeny (Schneirla, 1959). We define this system as *behavioral approach based on incentive motivation* (Depue & Collins, 1999).

The nature of this behavioral system, as well as the system associated with a consummatory phase of reward (discussed next), can be most efficiently described by using an affiliative object (e.g., a potential mate) as the rewarding goal object. Thus, an affiliative goal is referred to throughout this and the next sections. In the appetitive phase of affiliation (see Figure 20.1), specific, *distal* affiliative stimuli of potential bonding partners—for example, facial features and smiles, friendly vocalizations and gestures, and bodily features (Porges, 1998)—serve as unconditioned incentive stimuli based on their distinct patterns of sensory properties, such as smell, color, shape, and temperature (Di Chiara & North, 1992; Hilliard et al., 1998). For instance, Breiter, Aharon, Kahneman, Dale, and Shizgal (2001) and Aharon et al. (2001) have shown that even passive viewing of attractive female faces unconditionally activates the anatomical areas that integrate reward, incentive motivation, and approach behavior in heterosexual males. These incentives are inherently evaluated as positive in valence and activate incentive motivation, increased energy through sympathetic nervous system activity, and forward locomotion as a means of bringing individuals into close proximity (Di Chiara & North, 1992). Moreover, the incentive state is inherently rewarding but in a highly activated manner,

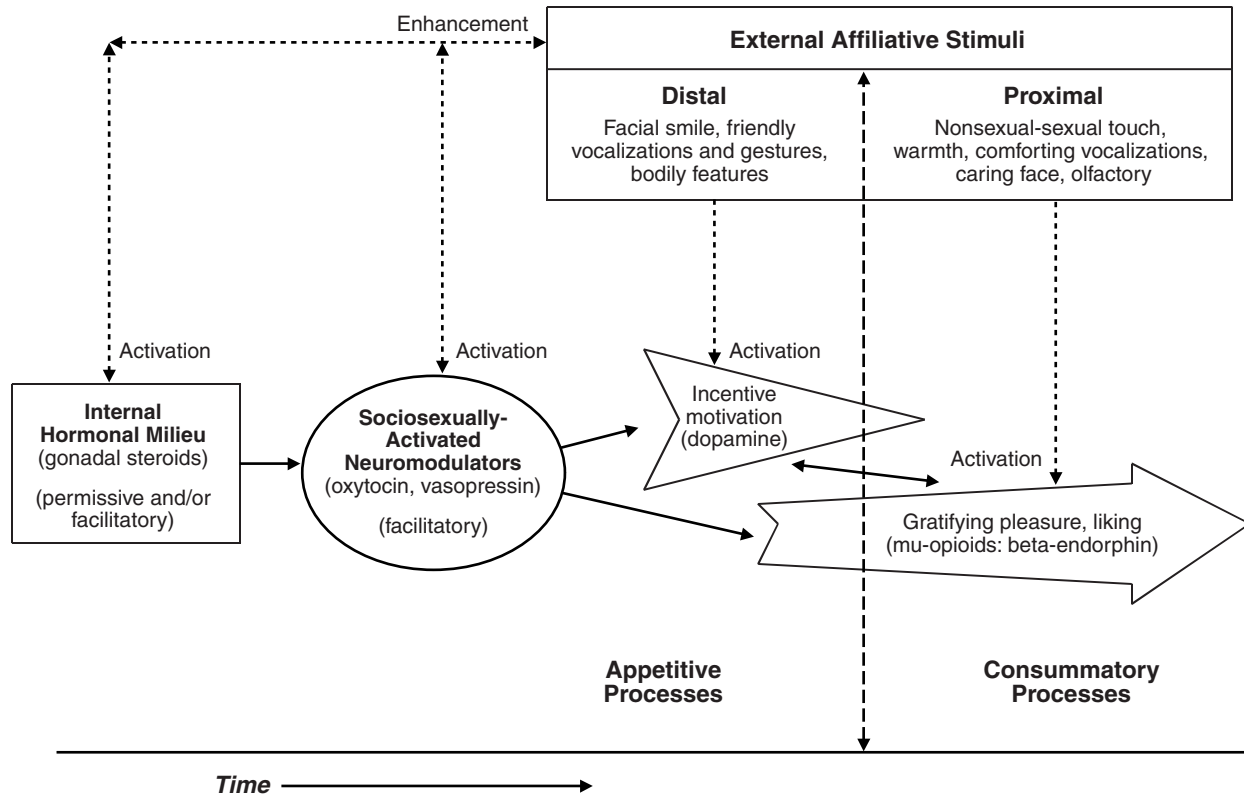

Figure 20.1 The development and maintenance of affiliative bonds across two phases of reward. Distal affiliative stimuli elicit an incentive-motivated approach to an affiliative goal, accompanied by strong emotional-motivational feelings of wanting, desire, and positive activation. The approach phase ensures not only sociosexual interaction with an affiliative object, but also acquisition of a memory ensemble or network of the context in which approach, reward, and goal acquisition occur. Next, proximal affiliative stimuli emanating from interaction with the affiliative object elicit strong feelings of consummatory reward, liking, and physiological quiescence, all of which become associated with these stimuli as well as the context predictive of reward. As discussed in the text, dopamine encodes the incentive salience of contextual stimuli predictive of reward during the approach phase and, in collaboration with consummatory reward mediated by μ -opiate, encodes the incentive salience of proximal stimuli directly linked to the affiliative object. The end result of this sequence of processes is an incentive-encoded affiliative memory network that continues to motivate approach toward and interaction with the affiliative object. Specialized processes ensure that affiliative stimuli are weighted as significant elements in the contextual ensembles representing affiliative memory networks. These specialized processes include the construction of a contextual ensemble via affiliative stimulus-induced opiate potentiation of dopamine processes and the influence of permissive and/or facilitatory factors such as gonadal steroids, oxytocin, and vasopressin on (1) sensory, perceptual, and attentional processing of affiliative stimuli and (2) formation of social memories. See Depue and Morrone-Strupinsky (in press) for details.

and animals will work intensively to obtain that reward without evidence of satiety (Depue & Collins, 1999).

In humans, the incentive state is associated with subjective feelings of desire, wanting, excitement, elation, enthusiasm, energy, potency, and self-efficacy that are distinct from, but typically co-occur with, feelings of pleasure and liking (Berridge, 1999; Watson & Tellegen, 1985). This subjective experience is concordant with the nature of the lower-order traits of social dominance, achievement, endurance, persistence, efficacy, activity, and energy that all load strongly on the *agency* personality factor (see earlier discussion) and with the adjectives that define the subjective *state* of positive affect that is so

closely associated with agentic extraversion (activated, peppy, strong, enthused, energetic; Watson & Tellegen, 1985). Therefore, we have proposed that agentic extraversion reflects the activity of a behavioral approach system based on *positive incentive motivation*.

When close proximity to a rewarding goal is achieved, incentive-motivational approach gives way to a consummatory phase of goal acquisition (Herbert, 1993). In this phase, specific *interoceptive* and *proximal exteroceptive* stimuli related to critical primary biological aims elicit behavioral patterns that are relatively specific to those conditions (e.g., sexual, social, or food-related; Blackburn et al., 1989; Hilliard et al., 1998; MacLean, 1986; Timberlake &

Silva, 1995). Performance of these behavioral patterns is inherently rewarding (Berridge, 1999). In the case of potential mate acquisition, examples of affiliative behavioral patterns are courtship, gentle stroking and grooming, mating, and certain maternal patterns such as breast-feeding, all of which may include facial, caressive tactile, gestural, and certain vocal behaviors (Polan & Hofer, 1998). Tactile stimulation may be particularly effective in activating affiliative reward processes in animals and humans (Fleming, Korsmit, & Deller, 1994). Significantly, light, pleasant touch that occurs to caress-like, skin-to-skin contact between individuals is transmitted by different afferents from hard or unpleasant touch (Olausson et al., 2002); light, pleasant touch is transmitted by slow-conducting, unmyelinated afferents that project to the insular cortex but not to somatosensory areas S1 and S2, whereas hard, unpleasant touch is transmitted by fast-conducting myelinated afferents to S1 and S2 (anterior parietal). The insular cortex is a paralimbic region known to integrate several sensory modalities, including autonomic, gustatory, visual, auditory, and somatosensory, to characterize the emotional nature of sensory input (Damasio, 2003; Mesulam, 1990).

As opposed to an incentive motivational state of activation, desire, and wanting, the expression of *consummatory* behavioral patterns elicits intense feelings of pleasure, gratification, and liking, plus physiological quiescence characterized by rest, sedation, anabolism, and parasympathetic nervous system activity, thereby reinforcing the production and repetition of those behaviors (Berridge, 1999; Di Chiara & North, 1992; Porges, 1998, 2001). Thus, whereas appetitive approach processes bring an individual into contact with unconditioned incentive stimuli, consummatory processes bring behavior to a gratifying conclusion (Hilliard et al., 1998). Whether the pleasurable state generated in affiliative interactions shares a common neurobiology with the pleasure generated by other consummatory behaviors (e.g., feeding) is not certain but is assumed by some to be so (Di Chiara & North, 1992; Panksepp, 1998).

The core content of affiliation scales seems to reflect the operation of neurobehavioral processes that (1) create a warm, affectionate, gratifying subjective emotional state elicited by others, which (2) motivate close interpersonal behavior. Our hypothesis is that the subjective experience of warmth and affection reflects the *capacity to experience consummatory reward that is elicited by a broad array of affiliative stimuli* (Depue & Morrone-Strupinsky, in press). This capacity is viewed as providing the key element utilized in additional psychobiological processes that permit the development and maintenance of longer-term affective bonds, defined as long-term selective social attachments

observed most intensely between infants and parents and between adult mates, and that are characteristic of social organization in human and other primate societies (Gingrich, Liu, Cascio, Wang, & Insel, 2000; Wang et al., 1999). It is important to emphasize that a core capacity for affiliative reward and bonding is not viewed as a sufficient determinant of close social relationships, only as a necessary one, a *sine qua non*. Such affiliative reward is hypothesized to underlie all human social relationships having a positive affective component. Other interpersonal constructs of sociability, attachment, and separation anxiety are accordingly viewed as either broader than affiliation, as defined here, and/or as based on different neurobehavioral systems (see Depue & Morrone-Strupinsky, in press, for a full discussion).

Through Pavlovian associative learning, the experience of reward generated throughout appetitive and consummatory phases is associated with previously affectively neutral stimulus contexts (objects, acts, events, places) in which pleasure occurred, thereby forming conditioned incentive stimuli that are predictive of reward and that have gained the capacity to elicit anticipatory pleasure and incentive motivation (Berridge, 1999; Ostrowski, 1998; Timberlake & Silva, 1995). Because of the predominance of symbolic (conditioned) processes in guiding human behavior in the absence of unconditioned stimuli, conditioned incentives are likely to be particularly important elicitors of *enduring* reward processes (Fowles, 1987). Thus, the acquisition and maintenance of a mate relationship, for example, depends closely on Pavlovian associative learning that links the experience of reward with (1) the salient contextual cues that predict reward during the appetitive phase (e.g., features of a laboratory cage) and (2) a mate's individualistic cues associated directly with consummatory reward (e.g., individual characteristics of a sexually receptive female mate; Domjan, Cusato, & Villarreal, 2000). Taken together, these processes support acquisition of affiliative memories, where contextual ensembles are formed and weighted in association with the reward provided by interaction with the potential mate.

Neurobiology of Incentive Motivation and Affiliative Reward

By drawing an association between traits and behavioral systems, that is, agentic extraversion and incentive motivation, affiliation and affiliative reward, we are able to utilize the behavioral neurobiology animal literature to discern the neurobiology associated with these behavioral systems and, by analogy, with the personality traits of agentic extraversion and affiliation. As reviewed recently (Depue & Collins, 1999), animal research demonstrates

that the positive incentive motivation and experience of reward that underlies a behavioral system of approach is dependent on the functional properties of the midbrain ventral tegmental area (VTA) dopamine (DA) projection system. DA agonists or antagonists in the VTA or nucleus accumbens (NAS), which is a major terminal area of VTA DA projections, in rats and monkeys facilitate or markedly impair, respectively, a broad array of incentive motivated behaviors. Furthermore, dose-dependent DA receptor activation in the VTA-NAS pathway facilitates the acute rewarding effects of stimulants, and the NAS is a particularly strong site for intracranial self-administration of DA agonists (Le Moal & Simon, 1991; Pich et al., 1997). DA agonists injected in the NAS also modulate behavioral responses to *conditioned* incentive stimuli in a dose-dependent fashion (Cador, Taylor, & Robbins, 1991; Robbins, Cador, Taylor, & Everitt, 1989; Wolterink, Cador, Wolterink, Robbins, & Everitt, 1989). In single-unit recording studies, VTA DA neurons are activated preferentially by appetitive incentive stimuli (Schultz, Dayan, & Montague, 1997). DA cells, most numerous in the VTA, respond vigorously to and in proportion to the magnitude of both conditioned and unconditioned incentive stimuli and in anticipation of reward (Schultz et al., 1997).

Incentive motivation is associated in humans with both positive *emotional* feelings, such as elation and euphoria, and *motivational* feelings of desire, wanting, craving, potency, and self-efficacy. In humans, DA-activating psychostimulant drugs induce both sets of feelings (Drevets et al., 2001). Neuroimaging studies of cocaine addicts found that during acute administration, the intensity of a subject's subjective euphoria increased in a dose-dependent manner in proportion to cocaine binding to the DA uptake transporter (and hence to DA levels) in the striatum (Volkow et al., 1997). Moreover, cocaine-induced activity in the NAS was linked equally strongly (if not more strongly) to motivational feelings of desire, wanting, and craving as to the emotional experience of euphoric rush (Breiter et al., 1997). The degree of amphetamine-induced DA release in the healthy human ventral striatum assessed by PET was correlated strongly with feelings of euphoria (Drevets et al., 2001). Hence, taken together, the animal and human evidence demonstrates that the VTA DA-NAS pathway is a primary neural circuit for incentive motivation and its accompanying subjective state of reward.

With respect to consummatory reward and affiliative behavior, a broad range of evidence suggests a role for endogenous opiates. Endogenous opiate release or receptor binding is increased in rats, monkeys, and humans by lacta-

tion and nursing, sexual activity, vaginocervical stimulation, maternal social interaction, brief social isolation, and grooming and other nonsexual tactile stimulation (Depue & Morrone-Strupinsky, in press; Keverne, 1996; Silk, Alberts, & Altmann, 2003). Opiate receptor (OR) antagonists naltrexone or naloxone in small doses apparently reduce the reward derived from social interactions because they increase attempts to obtain such reward, manifested as increases in the amount of maternal contact by young monkeys and solicitations for grooming and frequency of being groomed in mature female monkeys, which has been associated with increased cerebrospinal fluid levels of β -endorphin (Graves, Wallen, & Maestriepieri, 2002; Martel, Nevison, Simpson, Keverne, 1995). In addition, the endogenous opiate β -endorphin stimulates play behavior and grooming in juvenile rats, whereas naltrexone leads to reduced grooming of infants and other group members in monkeys and rats, and to maternal neglect in monkeys and sheep that is similar to the neglect shown by human mothers who abuse opiates (Keverne, 1996; Martel et al., 1995). Similarly, human females administered the opiate antagonist naltrexone showed an increased amount of time spent alone, a reduced amount of time spent with friends, and a reduced frequency and pleasantness of their social interactions relative to placebo. Such findings suggest that opiates provide a critical part of the neural basis on which primate sociality has evolved (Nelson & Panksepp, 1998). Particularly important is the relation between μ -opiates and grooming, because the primary function of primate grooming may well be to establish and maintain social bonds (Matheson & Bernstein, 2000).

Perhaps most relevant to affiliative reward is the mu (μ) OR family, which is the main site of exogenously administered opiate drugs (e.g., morphine) and of endogenous endorphins (particularly, β -endorphin; LaBuda, Sora, Uhl, Fuchs, 2000; Schlaepfer et al., 1998; Shippenberg & Elmer, 1998; Stefano et al., 2000; Wiedenmayer & Barr, 2000). μ ORs also appear to be the main site for the effects of endogenous β -endorphins and endogenous morphine on the subjective feelings in humans of *increased* interpersonal warmth, euphoria, well-being, and peaceful calmness, as well as of *decreased* elation, energy, and incentive motivation (Schlaepfer et al., 1998; Shippenberg & Elmer, 1998; Stefano et al., 2000; Uhl, Sora, & Wang, 1999).

The facilitatory effects of opiates on affiliative behavior are thought to be exerted by fibers that arise mainly from the hypothalamic arcuate nucleus and terminate in brain regions that typically express μ ORs. μ ORs may facilitate the rewarding effects associated with many motivated

behaviors (Nelson & Panksepp, 1998; Niesink, Vanderschuren, & van Ree, 1996; Olive, Koenig, Nannini, & Hodge, 2001; Olson, Olson, & Kastin, 1997; Stefano et al., 2000; Strand, 1999). For instance, whereas DA antagonists block appetitive behaviors in pursuit of reward but not the actual consumption of reward (e.g., sucrose; Ikemoto & Panksepp, 1996), μ OR-antagonists block rewarding effects of sucrose and sexual behavior, and in neonatal rats persistently impair the response to the inherently rewarding properties of novel stimulation (Herz, 1998). Rewarding properties of μ OR agonists are directly indicated by the facts that animals will work for the prototypical μ -agonists morphine and heroin and that they are dose-dependently self-administered in animals and humans (Di Chiara, 1995; Nelson & Panksepp, 1998; Olson et al., 1997; Shippenberg & Elmer, 1998). There is a significant correlation between an agonist's affinity at the μ OR and the dose that maintains maximal rates of drug self-administration behavior (Shippenberg & Elmer, 1998).

The rewarding effect of opiates may be especially mediated by μ ORs located in the NAS and VTA, both of which support self-administration of μ OR agonists that is attenuated by intracranially administered μ OR antagonists (David & Cazala, 2000; Herz, 1998; Schlaepfer et al., 1998; Shippenberg & Elmer, 1998). When opiate- and DA-specific antagonists were given prior to cocaine or heroin self-administration, the opiate antagonist selectively altered opiate self-administration, and DA antagonists selectively altered the response to the DA agonist cocaine (Shippenberg & Elmer, 1998). Destruction of DA terminals in the NAS also showed that opiate self-administration is independent of DA function, at least at the level of the NAS (Dworkin, Guerin, Goeders, & Smith, 1988). Furthermore, NAS DA functioning was specifically related to the incentive salience of reward cues but was unrelated to the hedonic state generated by consuming the rewards (Wyvell & Berridge, 2000). *Thus, DA and opiates appear to functionally interact in the NAS, but they apparently provide independent contributions to rewarding effects.* This appears to be particularly the case for the *acute* rewarding effects of opiates, which are thought to occur through a DA-independent system that is mediated through brain stem reward circuits, including the tegmental pedunculo-pontine nucleus (Laviolette, Gallegos, Henriksen, & van der Kooy, 2004).

Rewarding effects of opiates are also directly indicated by the fact that a range of μ OR agonists, when injected intracerebroventricularly or directly into the NAS, serve as unconditioned rewarding stimuli in a dose-dependent

manner in producing a conditioned place preference, a behavioral measure of reward (Narita, Aoki, & Suzuki, 2000; Nelson & Panksepp, 1998; Shippenberg & Elmer, 1998). VTA-localized μ ORs, particularly in the rostral zone of the VTA (Carlezon et al., 2000), mediate (1) rewarding effects such as self-administration behavior and conditioned place preference (Carlezon et al., 2000; Shippenberg & Elmer, 1998; Wise, 1998), (2) increased sexual activity and maternal behaviors (Callahan et al., 1996; Leyton & Stewart, 1992; van Furth & van Ree, 1996), and (3) the persistently increased play behavior, social grooming, and social approach of rats subjected to morphine in utero (Hol, Niesink, van Ree, & Spruijt, 1996). Indeed, microinjections of morphine or a selective μ OR agonist into the VTA produced marked place preferences, whereas selective antagonism of μ ORs prevented morphine-induced conditioned place preference (Olmstead & Franklin, 1997). Indeed, transgenic mice lacking the μ OR gene show no morphine-induced place preferences or physical dependence from morphine consumption, whereas morphine induces both of these behaviors in wild-type mice (Matthes et al., 1996; Simonin et al., 1998). Significantly, opiate but not oxytocin antagonists block the development of partner preference that is induced specifically by *repeated* exposure and *repeated* sexual activity in rodents (Carter, Lederhendler, & Kirkpatrick, 1997).

An *interaction* of DA and μ -opiates in the experience of reward throughout appetitive and consummatory phases of *affiliative* engagement appears to involve two processes. During the anticipatory phase of goal acquisition, μ OR activation in the VTA can increase DA release in the NAS and hence the experience of reward (Marinelli & White, 2000). Subsequently, the firing rate of VTA neurons decreases following delivery and consumption of appetitive reinforcers (e.g., food, sex, liquid; Schultz et al., 1997). At the same time, μ OR activation in the NAS (perhaps by opiate release from higher-threshold NAS terminals that colocalize DA and opiates; Le Moal & Simon, 1991) decreases NAS DA release, creating an opiate-mediated experience of reward associated with consummation that is independent of DA (Churchill, Rogues, & Kalivas, 1995). Thus, in contrast to the incentive motivational effects of DA during the anticipation of reward, opiates may subsequently induce calm pleasure and bring consummatory behavior to a gratifying conclusion. This may explain the fact that higher doses of μ OR agonists administered into the NAS can block the self-administration of certain psychostimulant drugs of abuse in animals and reduce appetitive behaviors

(Hyztia & Kiiannaa, 2001; B. Johnson & Ait-Daoud, 2000; Kranzler, 2000).

In sum, as illustrated in Figure 20.1, distal affiliative cues (e.g., friendly smiles and gestures, sexual features) serve as incentive stimuli that activate DA-facilitated incentive-reward motivation, desire, wanting, and approach to affiliative objects. As these objects are reached, more proximal affiliative stimuli (e.g., pleasant touch) strongly activate μ -opiate release, which promotes an intense state of pleasant reward, warmth, affection, and physiological quiescence and brings approach behavior to a gratifying conclusion. Throughout this entire sequence of goal acquisition, the contextual cues associated with approach to the goal, and the cues specifically related to the goal, are all associated with the experience of reward. It is beyond the scope of this chapter, but it is worth noting that DA and μ -opiates play a critical role in strengthening the association between these contextual cues and reward (Depue & Morrone-Strupinsky, in press). Thus, these two neuromodulators are critical to establishing our preferences and memories for particular contexts and affiliative cues predictive of reward.

Individual Differences in Dopamine Incentive and μ Opiate Receptor Reward Processes

Individual differences in agentic extraversion and affiliation are subject to strong genetic influence (Tellegen et al., 1988). If personality disturbance occurs in the region located at the extreme tails of individual difference distributions in the traits of agentic extraversion and affiliation, it is important to show that the neuromodulators associated with incentive motivation and affiliative reward are sources of individual differences in these behavioral systems. Animal research demonstrates that individual differences in DA functioning contribute significantly to variation in incentive-motivated behavior, as does much human work (Depue & Collins, 1999; Depue, Luciana, Arbisi, Collins, & Leon, 1994). Inbred mouse and rat strains with variation in the number of neurons in the VTA DA cell group or in several indicators of enhanced DA transmission show marked differences in behaviors dependent on DA transmission in the VTA-NAS pathway, including levels of spontaneous exploratory activity and DA agonist-induced locomotor activity and increased acquisition of self-administration of psychostimulants (Depue & Collins, 1999).

Similar findings for μ -opiates exist (Depue & Morrone-Strupinsky, in press). Individual differences in humans and rodents have been demonstrated in levels of μ OR expression and binding that are associated with a preference for

μ OR-agonists such as morphine (Uhl et al., 1999; Zubietta et al., 2001). In humans, individual differences in central nervous system (CNS) μ OR densities show a range of up to 75% between lower and upper thirds of the distribution (Uhl et al., 1999), differences that appear to be related to variation in the rewarding effects of alcohol in humans and rodents (Berrettini et al., 1997; De Waele et al., 1995; Gi-anoulakis et al., 1996; McCall et al., 2000a, 2000b; Olson et al., 1997).

Differences of this magnitude in the *expressive* properties of the μ OR gene could contribute substantially to individual variation in μ OR-induced *behavioral* expression via an effect on β -endorphin functional potency. For instance, one source of this individual variation is different single-nucleotide polymorphisms (SNPs) in the μ OR gene OPRM1 (Berrettini, Hoehe, Ferraro, DeMaria, & Gottheil, 1997; Bond et al., 1998; Gelernter, Kranzler, & Cubells, 1999). The most prevalent of these is A118G, which is characterized by a substitution of the amino acid Asn by Asp at codon 40, with an allelic frequency of 10% in a mixed sample of former heroin abusers and normal controls (Bond et al., 1998). Although this SNP did not bind all opiate peptides more strongly than other SNPs or the normal nucleotide sequence, it did bind β -endorphin 3 times more tightly than the most common allelic form of the receptor (Bond et al., 1998). Furthermore, β -endorphin is 3 times more effective in agonist-induced activation of G-protein-coupled potassium channels at the A118G variant receptor compared to the most common allelic form (Bond et al., 1998).

Genetic variation in μ OR properties is related to response to rewarding drugs, such as morphine, alcohol, and cocaine, and to opiate self-administration behavior in animals (Berrettini et al., 1997). For instance, when transgenic insertion was used to increase μ OR density specifically in mesolimbic areas thought to mediate substance abuse via VTA DA neurons, transgenic mice showed increased self-administration of morphine compared to wild-type mice, even when the amount of behavior required to maintain drug intake increased 10-fold (Elmer, Pieper, Goldberg, & George, 1995). Thus, the efficacy of morphine as a reinforcer was substantially enhanced in transgenic mice. Conversely, μ OR knock-out mice do not develop conditioned place preference and physical dependence on morphine, whereas morphine induces both of these behaviors in wild-type mice (Matthes et al., 1996).

Taken together, these studies suggest that genetic variation in DA and μ OR properties in humans and rodents is (1) substantial, (2) an essential element in the variation

in the rewarding value of DA and opiate agonists, and (3) critical in accounting for variation in the Pavlovian learning that underlies the association between contextual cues and reward, as occurs in partner and place preferences (Elmer et al., 1995; Matthes et al., 1996).

Anxiety or Neuroticism

Here we consider the nature and independence of anxiety and fear as behavioral systems as well as consider their neurobiological foundations.

Anxiety and Fear as Two Distinct Behavioral Systems

Adaptation to aversive environmental conditions is crucial for species survival, and at least two distinct behavioral systems have evolved to promote such adaptation. One system is fear (often labeled “harm avoidance” in the trait literature, but this is different from Cloninger, Svrakic, and Przybeck’s, 1993, harm avoidance, which actually assesses anxiety), which is a very specific behavioral system that evolved as a means of escaping unconditioned aversive stimuli that are inherently dangerous to survival, such as tactile pain, injury contexts, snakes, spiders, heights, approaching strangers, and sudden sounds. These stimuli are specific, discrete, and explicit and in turn elicit specific, short-latency, high-magnitude phasic responses of autonomic arousal, subjective feelings of panic, and behavioral escape. Specific, discrete, neutral stimuli associated with these unconditioned events elicit conditioned fear. Such conditioned stimuli elicit a different behavioral profile from that of unconditioned stimuli, in that freezing and suppression of operant behavior (i.e., behavioral inhibition), as opposed to active escape, characterize the former, though both response systems involve autonomic arousal, pain inhibition, and reflex potentiation.

There are, however, many aversive circumstances that do not involve specific, discrete, explicit stimuli that evolutionarily have been neurobiologically linked to subjective fear and escape. That is, there are many situations in which specific aversive cues do not exist; rather, the stimulus conditions are associated with an elevated *potential* risk of danger or aversive consequences. In such cases, no explicit aversive stimuli are present to inherently activate escape circuitries. Nevertheless, the stimuli can be unconditioned in nature, as in darkness, open spaces, unfamiliarity, and predator odors, or they can be conditioned contextual cues (general textures, colors, relative spatial locations, sounds) that have been associated with previous

exposure to specific aversive stimuli (Davis & Shi, 1999; Davis, Walker, & Lee, 1997; Fendt, Endres, & Apfelbach, 2003). Conceptually, these stimuli are characterized in common by unpredictability and uncontrollability—or, more simply, uncertainty.

To reduce the risk of danger in such circumstances, a second behavioral system evolved: *anxiety*. Anxiety is characterized by negative emotion or affect (anxiety, depression, hostility, suspiciousness, distress) that serves the purpose of informing the individual that, though no explicit, specific aversive stimuli are present, conditions are potentially threatening (White & Depue, 1999). This affective state, and the physiological arousal that accompanies it, continues or reverberates until the uncertainty is resolved. Associated responses that may functionally help to resolve the uncertainty are heightened attentional scanning of the uncertain environment and cognitive worrying and rumination over possible response-outcome scenarios. An important point is that no specific motor response is linked to anxiety, because no motor response is specified under stimulus conditions of uncertainty. Caution and locomotor modulation are necessary, but behavioral inhibition will not allow the individual to explore the environment to discover if danger is indeed lurking. An example is a deer entering an open meadow: Caution, slow approach, heightened attentional scanning, and enhanced cognitive activity are optimal, not freezing. This is in direct contradiction to Gray’s (1973) theory that the best marker for anxiety is behavioral inhibition; rather, conditioned stimulus fear is associated with such inhibition. Thus, Davis et al. (1997) and Barlow (2002) suggest that the stimulus conditions and behavioral characteristics of fear and anxiety are different, although a similar state of intense autonomic arousal is associated with both emotional states, rendering them similar at the subjective level. The prolonged negative subjective state of anxiety, however, distinguishes its subjective state from the rapid, brief state of panic associated with the presence of a specific fear stimulus.

There is another important difference between fear and anxiety at the trait level of analysis. In personality inventories, fear typically is represented as a primary or facet-level scale, not a higher-order factor (Tellegen & Waller, in press). Fear usually also is associated with a higher-order trait of constraint. In contrast, anxiety, which is typically referred to as neuroticism, is one of the most reliably identified higher-order traits and does not load highly on a constraint higher-order factor. This higher-order nature of anxiety but not fear is related to the fact that, just like

TABLE 20.1 Correlation between Trait Measures of Fear and Anxiety

agentive extraversion, the eliciting stimuli for anxiety occur frequently in a civilized society, whereas the specific stimuli that elicit fear do not. This means that anxiety represents a general behavioral system that is activated by a broad class of stimuli, whereas fear represents a more specific behavioral system that evolved to respond to specific stimuli critical for survival.

The trait literature supports the independence of anxiety and fear, which as personality traits are subject to distinct sources of genetic variation (Tellegen et al., 1988). As the averaged correlations derived from numerous studies in Tables 20.1, 20.2, and 20.3 show, the relation between neuroticism (anxiety) and harm avoidance (fear) is essentially zero (White & Depue, 1999). As shown in Tables 20.2 and 20.3, the magnitude of emotional distress and autonomic arousal elicited by discrete stimuli associated with physical harm (Table 20.2) is significantly related to harm avoidance but not neuroticism, whereas conditions of uncertainty associated with external evaluations of the self (Table 20.3) are significantly related to neuroticism but not harm avoidance (White & Depue, 1999). Furthermore, Table 20.2 shows that, in contrast to Gray's (1973, 1992) and Cloninger's (Cloninger et al., 1993) theoretical position that anxiety is associated with behavioral inhibition, it is harm avoidance rather than neuroticism that correlates significantly with indices of behavioral inhibition in contexts of physical danger. Indeed, one of the most reliable indices of conditioned fear in animals is behavioral inhibition (Davis

et al., 1997; LeDoux, 1998; Panksepp, 1998), which is not the case for stimulus-induced anxiety (Davis et al., 1997). These various findings suggest that anxiety and fear are distinctly different traits, and analysis of clinical anxiety disorders reached equivalent conclusions (Barlow, 2002).

Neurobiology of Anxiety

The psychometric independence of fear and anxiety is mirrored in their dissociable neuroanatomy. Species-specific unconditioned stimuli having an evolutionary history of danger eliciting fear and defensive motor escape, facial and vocal signs, autonomic activation, and antinociception, specifically from the lateral longitudinal cell column in the midbrain periaquiductal gray (PAG; see Figure 20.2; Bandler & Keay, 1996). In turn, PAG efferents converge on the ventromedial and rostral ventrolateral regions of the medulla, where somatic-motor and autonomic information, respectively, are integrated and transmitted to the spinal cord (Guyenet et al., 1996; Holstege, 1996). Although these processes can occur without a cortex (Panksepp, 1998), association of discrete, explicit neutral stimuli (fear conditioned stimulus) with an unconditioned stimulus and primary negative reinforcement occurs via cortical uni- and polymodal sensory efferents that converge on the basolateral complex of the amygdala (although crude representations of external stimuli can rapidly reach the basolateral amygdala subcortically from the thalamus; Aggleton, 1992; Davis et al., 1997; LeDoux, 1998). Fear conditioned stimuli elicit a host of behavioral, neuropeptide, and autonomic responses via output from the basolateral amygdala to the central

amygdala, which in turn sends functionally *separable* efferents to many hypothalamic and brain stem targets (Aggleton, 1992; LeDoux, Cicchetti, Xagoraris, & Romanski, 1990). In the case of fear conditioned stimulus, as noted earlier, the motor response is not escape but rather freezing or *behavioral inhibition*, which involves activation of the caudal ventrolateral cell column of the PAG, shown in Figure 20.2 (LeDoux, 1998).

The neuroanatomic distinction between fear and anxiety has been delineated by use of the fear-potentiated auditory-induced startle paradigm. In this paradigm, an established, explicit light conditioned stimulus activates a cell assembly representing the association among conditioned stimulus, unconditioned stimulus (e.g., shock), and tactile pain located in the basolateral amygdala. Excitation of this assembly by the conditioned stimulus activates efferents to the

central amygdala, which in turn monosynaptically potentiates startle reflex circuitry in the reticular nucleus of the caudal pons that is activated simultaneously by, for example, a loud, sudden noise. This potentiation of the startle reflex by a fear conditioned stimulus is *phasic* in nature, occurring almost immediately after light onset, but returning to baseline amplitude shortly after light offset (Davis et al., 1997). Lesions of the central amygdala reliably block explicit fear conditioned stimulus-potentiated startle and behavioral inhibition. In contrast, nondiscrete, contextually related aversive stimulation—for example, prolonged bright light in an unfamiliar environment, which are aversive unconditioned stimuli for nocturnal rats—elicits robust startle potentiation that endures *tonically* as long as the aversive conditions are present, even when the central amygdala is lesioned. These findings suggest that these types of stimulus conditions,

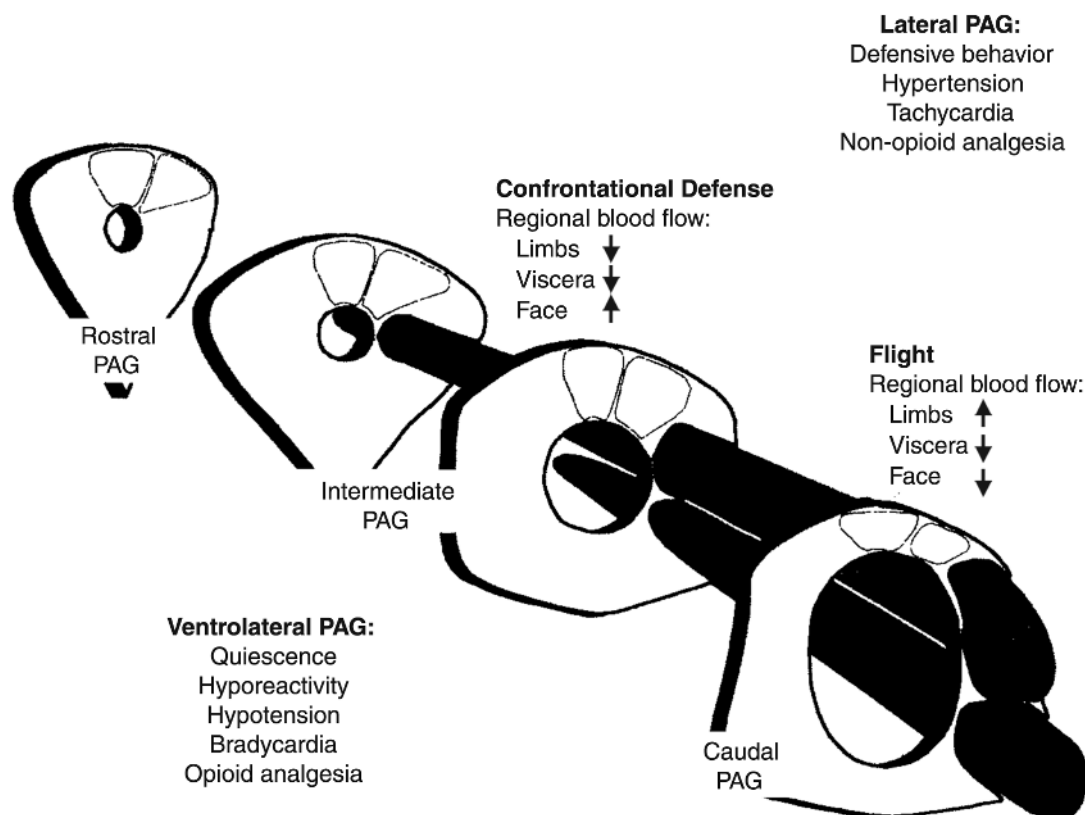

Figure 20.2 Schematic illustration of the lateral and ventrolateral neuronal columns in (from left to right) the rostral midbrain periaqueductal gray (PAG), the intermediate PAG (2 sections), and the caudal PAG. Injections of excitatory amino acids (EAA) in the lateral and ventrolateral PAG column evoke fundamentally opposite alterations in sensory responsiveness and somatic and autonomic adjustments. EAA injections made in the intermediate, lateral PAG evoke a confrontational defensive reaction, tachycardia, and hypertension associated with decreased blood flow to limbs and viscera and increased blood flow to extracranial vascular beds. EAA injections into the caudal, lateral PAG evoke flight, tachycardia, and hypertension associated with decreased blood flow to visceral and extracranial vascular beds and increased blood flow to limbs. In contrast, EAA injections into the ventrolateral PAG evoke cessation of all spontaneous activity (i.e., quiescence), a decreased responsiveness to the environment, hypotension, and bradycardia. The lateral and ventrolateral PAG also mediate different types of analgesia. *Source:* From Bandler & Keay, (1996).

which are typically associated with the elicitation of anxiety, rely on a different neuroanatomical foundation in generating an enduring potentiation of the startle reflex (Davis et al., 1997).

The enduring potentiating effects of nondiscrete, contextually related aversive stimuli on the startle reflex is dependent on a group of structures collectively referred to as the *extended amygdala*, which receives massive projections from basolateral and olfactory amygdala complexes, and which represents a macrostructure that is characterized by two divisions, central and medial (Heimer, 2003; McGinty, 1999). As shown in Figure 20.3, these two divisions originate from the central and medial nuclei of the amygdala and consist of cell groups that are distributed throughout the sublenticular area, bed nucleus of the stria terminalis (BNST), around striatal and pallidal structures, and back to merge specifically with the caudomedial region of the

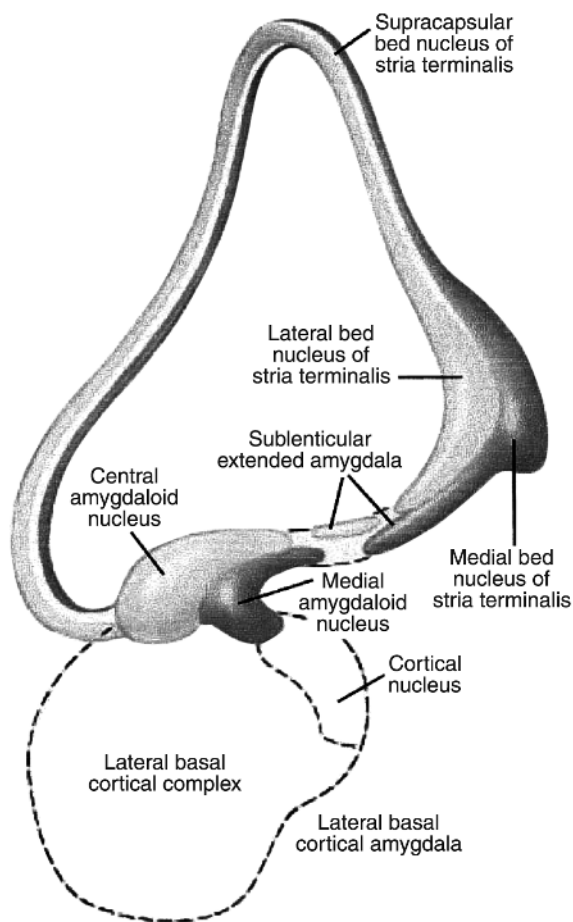

Figure 20.3 The central (dark gray) and medial (light gray) divisions of the extended amygdala, shown in isolation from the rest of the brain. *Source:* From “A New Anatomical Framework for Neuropsychiatric Disorders and Drug Abuse,” by L. Heimer, 2003, *American Journal of Psychiatry*, 160, pp. 1726–1739.

NAS. Contextual stimuli are conveyed to the BNST and other central extended amygdala regions via perirhinal plus basolateral amygdala (e.g., bright light) and parahippocampal + entorhinal + hippocampal (contextual stimuli) glutamatergic efferents (Annett, McGregor, & Robins, 1989; Bechara et al., 1995; Everitt & Robbins, 1992; Gaffan, 1992; Heimer, 2003; LeDoux, 1998; Selden, Everitt, Jarrod, & Robbins, 1991; Sutherland & McDonald, 1990). Viewing the sublenticular area and lateral BNST as a foundation for anxiety processes is supported in part by the fact that, in contrast to the central amygdala, (1) neurons in the sublenticular area show maximal prolonged responsiveness specifically to unfamiliar stimuli (Rolls, 1999) and (2) electrical stimulation or lesions of the BNST did not initiate or block, respectively, the behavioral inhibition elicited by an explicit fear conditioned stimulus (LeDoux et al., 1990), which mirrors the lack of association of behavioral inhibition with trait anxiety, discussed earlier.

Similar to the outputs from the central nucleus of the amygdala, most structures of the central division of the extended amygdala can transmit this motivationally relevant information to some or all hypothalamic and brain stem structures related to emotional expression (Heimer, 2003; Holstege, 1996). Whereas the basolateral complex of the amygdala is involved in pairing positive and negative reinforcement with stimuli that are discrete and explicit and that have been analyzed for their specific characteristics, at least the central division of the extended amygdala appears to associate *general contextual features and nonexplicit, nondiscrete* conditioned and unconditioned stimuli with reinforcement (e.g., light conditions, physical features, spatial relations; Davis & Shi, 1999; Davis et al., 1997; McDonald, Shammah-lagnado, Shi, & Davis, 1999). Thus, two emotional learning systems may have evolved: the basolateral amygdala to associate reinforcement with explicit, specific characteristics of objects (i.e., for fear), and the BNST to associate reinforcement with nonexplicit spatial and contextual stimulus aspects (i.e., for anxiety).

A major finding of importance in understanding the association between anxiety and the central extended amygdala is that injection of corticotropin-releasing hormone (CRH) into the BNST potentiates startle in a dose-dependent manner for up to 2 hours duration (Davis et al., 1997). It is not surprising, then, that lesions of the BNST or injection of a CRH antagonist in the BNST significantly attenuates both bright light- or CRH-enhanced startle without having any effect on discrete fear conditioned stimulus-potentiated startle (Davis et al., 1997). In contrast, lesions of the central amygdala eliminate the discrete fear conditioned stimulus-potentiated startle, but have no effect on CRH-enhanced startle.

Prolonged bright light-induced startle potentiation is also blocked by (1) lesions of the fornix, which carries hippocampal efferents conveying salient context to the BNST (Amaral & Witter, 1995); (2) glutamatergic antagonists injected into the BNST that block hippocampal efferent input; and (3) buspirone, a potent anxiolytic (Davis et al., 1997). Conversely, lesions of or glutamate antagonists injected in the central amygdala blocked fear conditioned stimulus-potentiated startle but had no effect on startle elicited by bright light conditions or on anxiolytic effects in the elevated + maze, where benzodiazepines have a robust anxiolytic effect (Davis et al., 1997; Treit, Pesold, & Rotzinger, 1993). The basolateral amygdala is involved in both bright light- and conditioned stimulus-potentiated startle due to processing of visual information, but not in CRH-enhanced startle.

Thus, with respect to potentiation of the startle reflex, there is a multivariate double dissociation of the central amygdala and the BNST. As summarized in Figure 20.4

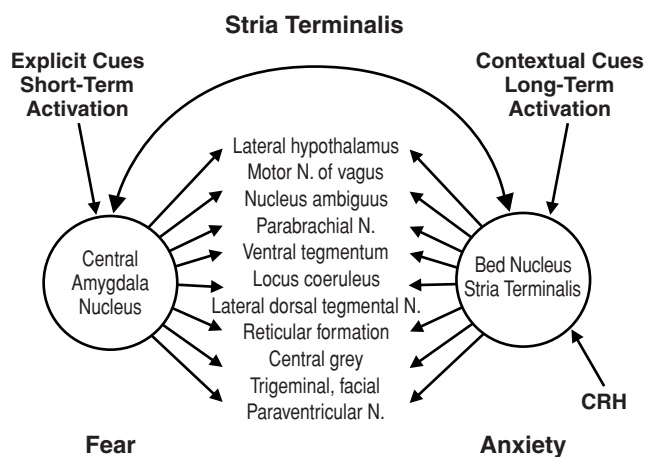

Figure 20.4 Hypothetical schematic suggesting that the central nucleus of the amygdala and the bed nucleus of the stria terminalis may be differentially involved in fear and anxiety, respectively. Both brain areas have highly similar hypothalamic and brain stem targets known to be involved in specific signs and symptoms of fear and anxiety. However, the stress peptide corticotropin-releasing hormone (CRH) appears to act on receptors in the bed nucleus of the stria terminalis rather than the amygdala, at least in terms of an increase in the startle reflex. Furthermore, the bed nucleus of the stria terminalis seems to be involved in the anxiogenic effects of a very bright light presented for a long time but not when that very same light was previously paired with a shock. Just the opposite is the case for the central nucleus of the amygdala, which is critical for fear conditioning using explicit cues such as a light or tone paired with aversive stimulation (i.e., conditioned fear). *Source:* From "Roles of the Amygdala and Bed Nucleus of the Stria Terminalis in Fear and Anxiety Measured with the Acoustic Startle Reflex," by M. Davis, D. Walker, and Y. Lee, 1997, *Annals of the New York Academy of Sciences*, 821, pp. 305–331.

(Davis et al., 1997), the nature of the different stimulus conditions that activate these two structures suggests that the amygdala connects explicit phasic stimuli that predict aversive unconditioned stimuli with rapidly activated evasive responses and subjective fear. In contrast, prolonged contextual and/or unfamiliar stimuli that connote uncertainty about expected outcome are associated with a neurobehavioral response system that coordinates activation of (1) the negative affective state of anxiety to inform the individual that the current context is uncertain and potentially dangerous, (2) autonomic arousal to mobilize energy for potential action, (3) selective attention to maximize sensory input at specified locations in the visual field, and (4) cognition to derive a response strategy. Nevertheless, as shown in Figure 20.4, efferents from the BNST and subnucleus innervate many of the same hypothalamic and brain stem regions as the central amygdala (Heimer, 2003), suggesting that fear and anxiety derive their somewhat similar subjective nature from common neuroendocrine and autonomic response systems (Davis et al., 1997; LeDoux, 1998; Rolls, 1999).

The significance of the prolonged startle-potentiation effects of CRH in the BNST is that CRH and the BNST appear to be integrators of behavioral, neuroendocrine, and autonomic responses to stressful circumstances (Leri, Flores, Rodaros, & Stewart, 2002; Pacak, McCarty, Palkovits, Kopin, & Goldstein, 1995; Shaham, Erb, & Stewart, 2000). This integration is accomplished by the activity of both the peripheral and central CRH systems. The peripheral system involves CRH neurons located in the paraventricular nucleus of the hypothalamus, which, when activated, initiate the series of events that ends in the release of cortisol from the adrenal cortex (Strand, 1999). Cortisol then circulates in the bloodstream and increases energy reserves (gluconeogenesis) and, if not excessive in quantity, can enhance neurotransmitters involved in modulating emotion and memory (Kim & Diamond, 2002).

In contrast, the central CRH system is composed of CRH neurons located in many different subcortical brain regions that modulate emotion, memory, and CNS arousal (Strand, 1999). Whereas the majority of CRH neurons in the CNS do not mediate the effects of stress, some of the CRH-containing regions that are important in mediating stress effects are illustrated in Figure 20.5. For instance, the basolateral amygdala detects discrete aversive stimuli associated with the stressful circumstances and activates the extensive array of CRH neurons located in the central amygdala. These CRH neurons project to many brain regions that modulate emotion, memory, and arousal, including the peripheral CRH neurons in the paraventricular nucleus in the hypothalamus

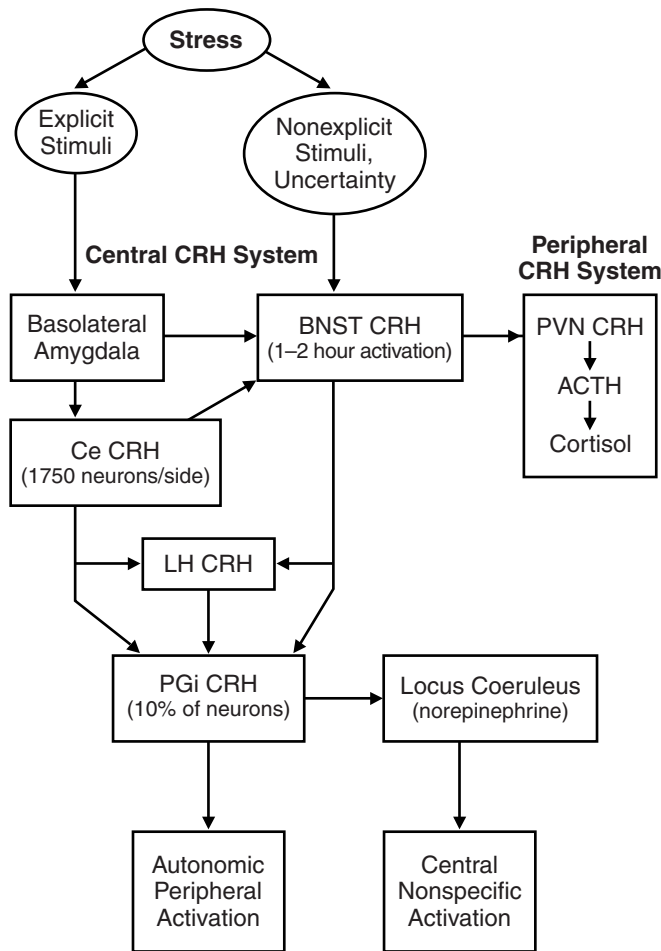

Figure 20.5 Components of the central and peripheral CRH systems. ACTH = Corticotropin hormone from the anterior pituitary; BNST = Bed nucleus of the stria terminalis; Ce = Central amygdala nucleus; LH = Lateral hypothalamus; PGI = Paragiganticocellularis; PVN = Paraventricular nucleus of the hypothalamus.

(Strand, 1999). Stress variables associated with context and uncertainty activate CRH neurons in the BNST, which have similar projection targets as the central amygdala (Erb, Salmaso, Rodaros, & Stewart, 2001; Macey, Smith, Nader, & Porrino, 2003; Shaham et al., 2000). Both the central amygdala and the BNST can activate CRH neurons in the lateral hypothalamus, a region that integrates CNS arousal. In turn, the lateral hypothalamic CRH projections modulate autonomic nervous system activity. Of particular importance, as illustrated in Figure 20.5, all three sources of CRH projections—the central amygdala, BNST, and lateral hypothalamus—innervate CRH neurons in the paragiganticocellularis (PGI; Aston-Jones, Rajkowski, Kubiak, Valentino, & Shiptley, 1996), which is located in the rostral ventrolateral area of the medulla in the brain stem. The PGI is a massive nu-

cleus that provides major integration of central and autonomic arousal and, in turn, coordinates and triggers arousal responses to urgent stimuli via two main pathways emanating from its own population of CRH neurons, which make up 10% of PGI neurons (Aston-Jones et al., 1996). One CRH pathway modulates the autonomic nervous system and hence peripheral arousal effects via projections to the intermediolateral cell column of the spinal cord, activating sympathetic preganglionic autonomic neurons.

The other CRH pathway modulates central arousal effects via activation of the locus coeruleus (LC), where PGI CRH innervation of the LC in humans and monkeys is dense (Aston-Jones et al., 1996). The LC, which is composed of ~20,000 neurons that provide the major source of norepinephrine (NE) in the brain, innervates the entire brain (Oades, 1985). LC neurons that release NE onto β -adrenergic receptors are responsible for producing a non-specific emotional activation via broadly collateralizing axons to the central nervous system (Aston-Jones et al., 1996), and this NE release to chronic stress is increased in inbred rat strains with high anxiety (Blizzard, 1988) and in Posttraumatic Stress Disorder patients (Charney, Grillon, & Bremner, 1998). This nonspecific emotional activation pattern constitutes a global urgent response system that responds to unpredicted events and hence facilitates behavioral readiness alerting (enhanced sensory processing) and attention (enhanced selection of stimuli; Aston-Jones et al., 1996), which are characteristic of states of anxiety in highly stress-reactive rodents and monkeys (Blizzard, 1988; Redmond, 1987). This central arousal can be enduring: PGI CRH activation of LC neurons endures and peaks 40 minutes after stimulation of the PGI (Aston-Jones et al., 1996). This persistent activation of spontaneous activity in the LC renders the short-lived, nonsalient stimuli of little effect on the LC, such that salient stimuli have an inordinate effect on LC activity and hence, in turn, on central activation. Thus, taken together, the central CRH neuron system is capable of activating a vast array of behaviorally relevant processes during stressful conditions, including activation of the peripheral CRH system.

CRH administration in rodents, as well as in transgenic mice that have an overproduction of CRH centrally (but not peripherally), generates specifically via CRH2 receptors anxiogenic effects, including reduced exploration of unfamiliarity and of the elevated T-maze, reduced sleep, reduced food intake and sexual activity, and increased sympathetic and behavioral signs of anxiety (Nie et al., 2004; Strand, 1999).

These findings, taken together, suggest that anxiety is essentially a stress-response system that relies on a network of

CRH neuron populations to modulate behaviorally relevant responses to the stressor. The most potent factors in determining the magnitude of a stressor are the very psychological factors that are eliciting stimuli of the anxiety system: uncontrollability, unpredictability, unfamiliarity, unavailability, and uncertainty. For example, an animal that can control shock shows little evidence of stress, but the animal that is yoked to the first animal and receives shock without control shows severe behavioral and physiological effects of stress. Thus, it is not the physical nature of the shock that is stressful, but the psychological factor of uncontrollability and unpredictability. Furthermore, from the standpoint of trait anxiety or neuroticism, the strongest primary or facet scale in the higher-order factor of anxiety in Tellegen's personality questionnaire is termed *Stress Reactivity* due to the stress-related content of items loading on the scale (Tellegen & Waller, in press).

Nonaffective Constraint or Impulsivity

Here we consider the nature of impulsivity and place this construct within a perspective that emphasizes nonaffective constraint as a major underlying neurobehavioral system. We also explore the neurobiology of nonaffective constraint as a modulatory system.

Delimiting the Heterogeneity of Impulsivity/Constraint

Impulsivity comprises a heterogeneous cluster of lower-order traits that includes sensation seeking, risk taking, novelty seeking, boldness, adventuresomeness, boredom susceptibility, unreliability, and unorderliness. This lack of specificity is reflected in the fact that the content of the measures of impulsivity is heterogeneous, and that not all of these measures are highly interrelated. We (Depue & Collins, 1999) demonstrated elsewhere that at least three different neurobehavioral systems may underlie this trait complex:

1. *Positive incentive motivation*, associated with exploration of novel stimulus conditions.
2. *Low fear*, as indicated in risk taking, attraction to physically dangerous activities, and lack of fear of physical harm.
3. *Low levels of a nonaffective form of impulsivity*, which results in disinhibition of the earlier neurobehavioral systems, as suggested by several researchers (Depue, 1995, 1996; Depue & Spont, 1986; Panksepp, 1998; Spont, 1992; Zuckerman, 1994).

As a means of disentangling and clarifying this complexity (see Figure 20.6), we plotted the trait loadings derived in 11 studies (see Appendix) in which two or more multidimensional personality questionnaires were jointly factor-analyzed to derive general, higher-order traits of personality. All studies identified a higher-order trait of impulsivity that *lacks affective content*, which in Figure 20.6 was labeled *constraint* following Tellegen (Tellegen & Waller, in press), who introduced the term to emphasize its independence from emotional traits such as extraversion and neuroticism. All studies also found constraint to be orthogonal to a general, higher-order extraversion trait. Figure 20.6 shows a continuous distribution of traits within the two intersecting orthogonal dimensions of extraversion and constraint. Nevertheless, three relatively homogeneous clusterings of traits can be delineated on the basis of the position and content of traits, relative to extraversion and constraint. First, lower-order traits associated with agentic extraversion (sociability, dominance, achievement, positive emotions, activity, energy) cluster at the high end of the extraversion dimension without substantial association with constraint. A tight clustering of most of these traits to extraversion is evident. Second, various traits of impulsivity that *do not incorporate strong positive affect* (e.g., conscientiousness) cluster tightly around the high end of the constraint dimension without substantial association with extraversion; Eysenck's psychoticism trait and various aggression measures are located at the low end of constraint and show little association with extraversion. Third, all but one trait measure of impulsivity that *incorporate positive affect* (sensation seeking, novelty seeking, risk taking) are located within the dashed lines in Figure 20.6 and are moderately associated with both extraversion and constraint. Thus, currently, most trait models of personality separate a nonaffective form of impulsivity and extraversion into distinct traits, although the terms used for the former vary from conscientiousness (P. Costa & McCrae, 1992; Goldberg & Rosolack, 1994) to constraint (Tellegen & Waller, in press) and impulsivity-unsocialized sensation seeking (Zuckerman, 1994).

Conceptually, the complexity of impulsivity can be clarified by hypothesizing that *nonaffective* constraint lacks ties to a specific motivational-emotional system (Depue & Collins, 1999). As discussed later, a vast body of animal and human literature demonstrates that constraint so conceived functions as a central nervous system variable that modulates the threshold of stimulus elicitation of motor behavior, both positive and negative emotions, and cognition (Coccaro & Siever, 1991; Depue, 1995, 1996; Depue & Spont, 1986; Panksepp, 1998; Spont, 1992; Zald & Depue, 2001; Zuck-

Figure 20.6. A plotting of loadings of personality traits derived in 11 studies in which more than one multidimensional personality questionnaire was jointly factor-analyzed as a means of deriving general traits of personality. All of these studies defined a general nonaffective impulsivity trait, referred to as constraint (horizontal dimension in the figure), that was separate from the general extraversion trait (vertical dimension in the figure). The figure illustrates three clusterings of traits: an extraversion cluster at the high end of the extraversion dimension; conscientiousness and psychoticism-aggression cluster at the high and low end of the constraint dimension, respectively; and an impulsivity/sensation seeking cluster within the dashed lines. The figure illustrates that extraversion and nonaffective constraint dimensions are generally identified and found to be orthogonal, and that impulsivity/sensation seeking traits associated with strong positive affect arise as a joint function of the interaction of extraversion and constraint. See Appendix A for the identity of the trait measure abbreviations with numbers, the questionnaires to which the abbreviations correspond, and the studies providing the trait loadings. *Source:* From “Neurobiology of the Structure of Personality: Dopamine, Facilitation of Incentive Motivation, and Extraversion,” by R. Depue and P. F. Collins, 1999, *Behavioral and Brain Sciences*, 22, pp. 491–569.

erman, 1994). This formulation is consistent with findings that low constraint is associated in both animals and humans with a generalized motor-cognitive-affective impulsivity but is not preferentially associated with any specific motivational system (Depue & Spont, 1986; Spont, 1992; Zald & Depue, 2001). Alternatively, *affective* impulsivity emerges from the interaction of nonaffective constraint with other

distinct affective-motivational systems, such as positive incentive motivation-agentive extraversion (as in Figure 20.6) and anxiety-neuroticism.

Elicitation of behavior can be modeled neurobiologically by use of a minimum threshold construct, which represents a central nervous system weighting of the external and internal factors that contribute to the probability of re-

response expression (Depue & Collins, 1999). External factors are characteristics of environmental stimulation, including magnitude, duration, and psychological salience. Internal factors consist of both state (e.g., stress-induced endocrine levels) and trait biological variation. We propose that nonaffective constraint is the personality trait that reflects the greatest CNS weight on the construct of a minimum response threshold. As such, constraint exerts a general influence over the elicitation of any emotional behavior, and hence constraint is not preferentially associated with any specific neurobehavioral-motivational system. In this model, other higher-order personality traits would thus reflect the influence of neurobiological variables that strongly contribute to the threshold for responding, such as DA in the facilitation of incentive-motivated behavior, μ -opioids in the experience of affiliative reward, and CRH in the potentiation of anxiety.

Neurobiology of Nonaffective Constraint

The important question is what type of CNS variables could provide a major weighting of behavioral elicitation thresholds. Functional levels of neurotransmitters that provide a strong, relatively generalized *tonic inhibitory* influence on behavioral responding would be good candidates as significant modulators of a response elicitation threshold, and hence would likely account for a large proportion of the variance in the trait of nonaffective constraint. We and others previously (Coccaro & Siever, 1991; Depue, 1995, 1996; Depue & Spont, 1986; Panksepp, 1998; Spont, 1992; Zald & Depue, 2001; Zuckerman, 1994) and Lesch (1998) most recently suggested that serotonin (5HT), acting at multiple receptor sites in most brain regions, is such a modulator (Azmitia & Whitaker-Azmitia, 1997; Tork, 1990). As reviewed many times in animal and human literatures (Coccaro & Siever, 1991; Coccaro et al., 1989; Depue, 1995, 1996; Depue & Spont, 1986; Lesch, 1998; Spont, 1992; Zald & Depue, 2001; Zuckerman, 1994), 5HT modulates a diverse set of functions (including emotion, motivation, motor, affiliation, cognition, food intake, sleep, and sexual activity) and sensory reactivity (such as nociception, sensitization to auditory and tactile startle stimuli, and escape latencies following PAG stimulation) and is associated with many clinical conditions, including violent suicide across several types of disorder, Obsessive-Compulsive Disorder, disorders of impulse control, aggression, depression, anxiety, arson, and substance abuse (Coccaro & Siever, 1991; Depue & Spont, 1986; Lesch, 1998; Spont, 1992). Furthermore, *reduced* 5HT functioning in

animals (Depue & Spont, 1986; Spont, 1992) and humans (Coccaro et al., 1989) is accompanied by *irritability* and *hypersensitivity* to stimulation in most sensory modalities (Spont, 1992), which may be due to the important role played by 5HT in the inhibitory modulation of sensory input at several levels of the brain (Azmitia & Whitaker-Azmitia, 1997; Tork, 1990), as well as to significant 5HT modulation of the lateral hypothalamic region that activates autonomic reactivity under stressful conditions (Azmitia & Whitaker-Azmitia, 1997). Thus, 5HT plays a substantial modulatory role in general neurobiological functioning that affects many forms of motivated behavior. In this sense, nonaffective constraint might be viewed as reflecting the influence of the CNS variable of 5HT, which we refer to later as *neural constraint*.

An important but difficult area of research is to determine which personality traits best assess the general modulatory role of 5HT. As a beginning, we found that 5HT agonist-induced increases in serum prolactin secretion were correlated significantly and specifically only with the Constraint/Impulsivity scale (-0.44 , $p < .01$) from Tellegen's personality questionnaire of 13 primary scales (Depue, 1995, 1996).

Conceptualizing Individual Differences Underlying Personality Traits

As discussed earlier, models of elicitation of behavioral processes often employ a minimum threshold that represents a central nervous system weighting of the external and internal factors that contribute to initiation of those processes (Depue & Collins, 1999). In addition to the effects of neural constraint (5HT; or nonaffective constraint at the behavioral level), the threshold is weighted most strongly by the joint function of two main variables: magnitude of eliciting stimulation and level of postsynaptic receptor activation of the neurobiological variable thought to contribute most variance to the behavioral process in question, such as DA to incentive motivation, μ -opioids to affiliative reward, and CRH to anxiety. The relation between these two variables is represented in Figure 20.7 as a trade-off function (White, 1986), where pairs of values (of stimulus magnitude and receptor activation) specify a diagonal representing the minimum threshold value for elicitation of a behavioral process. Findings reviewed earlier show that agonist-induced *state* changes in DA, μ OR, and CRH activation influence the threshold of incentive motivated behavior, affiliative reward, and anxiety, respectively. Because the two input variables (stimulus magnitude and receptor activation) are interactive, independent variation in

Figure 20.7 A minimum threshold for elicitation of a behavioral process (e.g., incentive motivation-positive affect, affiliative reward-affection, anxiety-negative affect) is illustrated as a trade-off function between eliciting stimulus magnitude (left vertical axis) and *variable X* (e.g., dopamine, μ -opiate, CRH) postsynaptic receptor activation (horizontal axis). Range of effective (eliciting) stimuli is illustrated on the right vertical axis as a function of level of receptor activation. Two hypothetical individuals with low and high *trait* postsynaptic receptor activation (demarcated on the horizontal axis as A and B, respectively) are shown to have narrow (A) and broad (B) ranges of effective stimuli. Threshold effects due to serotonin modulation are illustrated as well.

either one not only modifies the probability of eliciting the behavioral process, but it also simultaneously modifies the value of the other variable that is required to reach a minimum threshold of elicitation. Finally, individual variation in variables that significantly modulate the threshold, especially 5HT-related neural constraint (or nonaffective constraint), would serve as a source of modulation of the threshold of elicitation of *all* behavioral processes. This is shown for 5HT in Figure 20.7.

A threshold model allows behavioral predictions that help to conceptualize the effects of individual differences in neurobiological functioning on personality traits. A trait dimension of postsynaptic receptor activation of variable *X* (e.g., DA, μ -opiate, or CRH) is represented on the horizontal axis of Figure 20.7, where two individuals with divergent trait levels are demarcated: A (low trait level) and B (high trait level). These two divergent individuals may be used to illustrate the effects of trait differences in variable *X* receptor activation on elicitation of behavioral processes (e.g., incentive-motivated behavior, affiliative reward, or anxiety).

As Figure 20.7 indicates, for any given eliciting stimulus, the degree of variable *X* reactivity will, on average, be larger in individual B versus A. Hence, the subjective

emotional and motivational experiences that are facilitated by variable *X* (e.g., incentive, affection, anxiety) will also be more enhanced in B versus A (Depue & Collins, 1999; Depue & Morrone-Strupinsky, in press). In addition, the difference between individuals A and B in magnitude of subjective experience may contribute to variation in the contemporaneous encoding of a stimulus's intensity or salience (a form of state-dependent learning) and, hence, in the stimulus's encoded salience in subsequent memory consolidation. Accordingly, individuals A and B may develop differences in the capacity of mental representations of (incentive, affiliative, anxiety) contexts to activate the relevant motivational (incentive, affiliative, anxiety) processes, which is significant due to the predominant motivation of behavior in humans by symbolic representations of goals.

If individual differences in encoding apply across the full range of stimulus magnitudes, trait differences in the reactivity of variable *X* may have marked effects on the *range* of effective (i.e., eliciting) stimuli. This is illustrated in Figure 20.7, where the right vertical axis represents the range of effective (eliciting) stimuli. Increasing trait levels of variable *X* (horizontal axis) are associated with an increasing efficacy of weaker stimuli (left vertical axis) and, thus, with an increasing range of effective stimuli (right vertical axis). In Figure 20.7, individuals A and B are shown to have a narrow versus broad range, respectively. Significantly, the broader range for individual B suggests that, on average, B will experience more frequent elicitation of subjective emotional experiences associated with variable *X* activity (incentive, affection, anxiety). This means that the probability at any point in time of being in a variable *X*-facilitated state for individual B is higher than for A. Therefore, when subsequent relevant stimuli are encountered, their subjectively evaluated magnitude will show a stronger positive bias for B than for A. Thus, trait differences in variable *X* may *proactively* influence the evaluation and encoding of relevant stimuli and may not be restricted to *reactive* emotional processes. This raises the possibility of variation in the *dynamics* of behavioral engagement with the environment. A positive relation between state variable *X* activation and stimulus efficacy in the threshold model suggests that, as an initial stimulus enhances variable *X* activation, the efficacy of subsequently encountered stimuli may be increased proportionally to the degree of the initial variable *X* activation. Under conditions of strong variable *X* activation, perhaps even previously subthreshold stimuli may come to elicit behavioral processes (incentive, affiliative reward, anxiety).

THE INTERACTIVE NATURE OF EMOTIONAL TRAITS AND CONSTRAINT

Three of the higher-order personality traits discussed (agentic extraversion, affiliation, anxiety) provide the qualitative emotional content of contemporaneous behavior, depending on which neurobehavioral-motivational system is being elicited at any point in time. The fourth trait, nonaffective constraint, modulates the probability of elicitation of all of those systems. As the very construct of personality connotes, however, the affective or emotional *style* of an individual is determined by the interaction of all four higher-order traits. This means that differential strength between these personality traits, or differential reactivity of their underlying neurobehavioral systems, will determine the relative predominance of particular affective or emotional behavior in individuals. We now consider some of these relevant trait interactions as preparatory discussion for the model of personality disturbance that follows.

Agentic Extraversion \times Anxiety

Differential relative strength of the traits of agentic extraversion and anxiety has a substantial influence on the predominant affective or emotional style of an individual. Agentic extraversion is associated with a highly positive affective state, whereas anxiety is associated with a negative affective state. Moreover, both traits are associated with *general* neurobehavioral systems, meaning that they both are subject to frequent elicitation by a broad class of stimuli (incentives and uncertainty, respectively). As illustrated in Figure 20.8, the interaction of these two traits leads to various types of affective style depending on the values of the two traits. The upper right (positive) and lower left (negative) quadrants manifest the greatest contrast and consistency in affective styles, whereas the affective style of individuals in the upper left quadrant is mixed, depending on the relative salience of the most recent incentive versus uncertainty context. The lower right quadrant is characterized by both low positive and negative affective activation and therefore manifests as impoverished affective-emotional behavior reminiscent of clinical descriptions of schizoid behavior.

Agentic Extraversion \times Affiliation

The nature of an individual's interpersonal behavior is dependent on the relative strength of agentic extraversion and affiliation. Agentic extraversion is associated with social

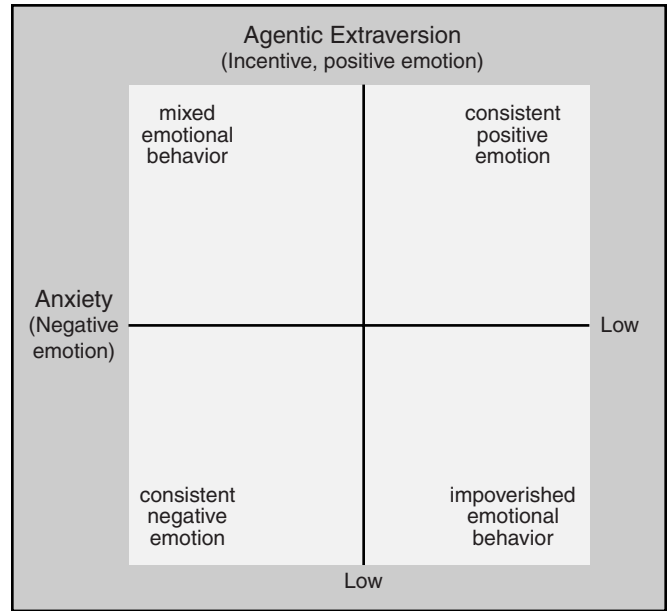

Figure 20.8 Interaction of the higher-order personality traits of agentic extraversion and anxiety. See text for details.

engagement and dominance, whereas affiliation reflects the capacity to experience reward from affiliative interactions. As discussed in the chapter's introduction, theories and research on interpersonal behavior have demonstrated that these two traits are independent and characterize most of the variance in interpersonal behavior. As illustrated in Figure 20.9, their interaction produces substantive differences in interpersonal style. Affiliation at the high end modulates the dominance and competitive aggression of agentic extraversion, creating an *amiable* interpersonal style, ranging from follower to leader depending on the level of agentic extraversion. Perhaps more relevant to personality disturbance, the low end of affiliation manifests as aloof, cold, and uncaring, which ranges from isolated and submissive to manipulative and domineering with increasing levels of agentic extraversion. The lower left quadrant is reminiscent of clinical descriptions of schizoid behavior, whereas the lower right is more in keeping with antisocial behavior.

Affiliation \times Separation Anxiety

An additional trait interaction would seem particularly relevant to characterizing interpersonal behavior in personality disturbance: an interaction between affiliation and separation anxiety or distress. The latter trait is rarely assessed in personality inventories, but it is a significant influence in most interpersonal relations at one

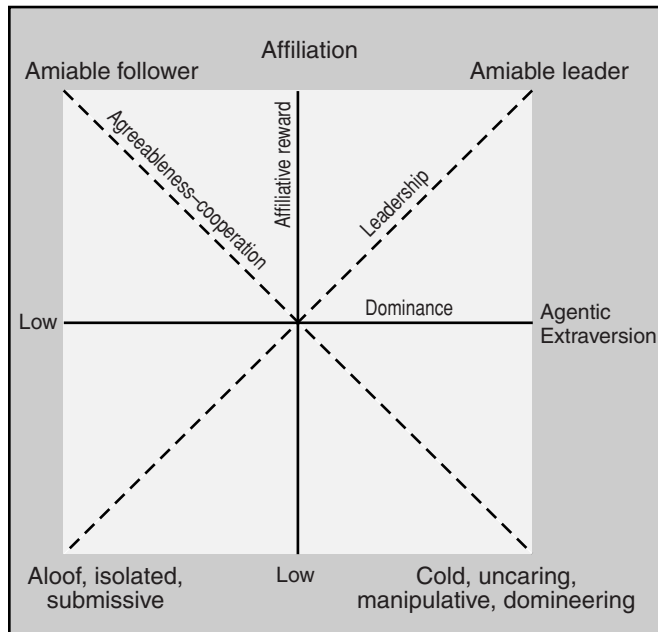

Figure 20.9 Interaction of the higher-order personality traits of agentic extraversion and affiliation. See text for details.

time or another and becomes impairing at extreme levels. Although manifestation of separation anxiety or distress is correlated with the existence of an affiliative bond, we take the position with others (Insel, 1997; Nelson & Panksepp, 1998; Panksepp, 1998; Young, Wang, & Insel, 1998) that processes underlying affiliative bonding are not the same as those involved in social separation distress. Affectively, affiliation and separation are distinctly different and not two sides of a coin. Separation is characterized by the presence of frustration, protest, and anxiety, and not just the absence of warmth and pleasure (and vice versa). In fact, there are data that support a bidimensional organization of affiliation and separation distress, because the neural pathways underlying affiliative engagement (e.g., maternal behavior) are different from those that allow for inhibition of separation distress (Eisenberger, Lieberman, & Williams, 2003; Insel, 1997; Nelson & Panksepp, 1998).

In behavioral terms, separation anxiety or distress may reflect the anxiety of *uncertainty* generated by removal of protective, supportive, safety cues. From a broader evolutionary perspective, separation leading to social isolation can be characterized as unconditionally aversive, having *no discrete, explicit stimulus source*—similar to the human experience of being in the dark (Davis & Shi, 1999; Davis et al., 1997; White & Depue, 1999). In humans, social isolation, rejection, and/or ostracism generates a sense of anxiety, guilt, and apprehension. Put differently, separa-

tion anxiety or distress may in part reflect a very basic neurobehavioral anxiety system that serves to motivate attempts to reverse social isolation via reintegration into a social group (Barlow, 2002; White & Depue, 1999). It may be that separation anxiety or distress is associated to other related traits such as rejection sensitivity and dependency, both of which reflect anxiety over social isolation. This system would be associated with neural networks involved in recognition of social uncertainty and rejection, experience of psychic pain (Eisenberger et al., 2003), and expression of anxiety.

Future research needs to establish the extent to which separation anxiety and the higher-order trait of anxiety are related: Do they reflect the same underlying neurobehavioral system elicited by uncertainty, or do they reflect distinct systems? The answer to this question may help to clarify the fundamental distinctions, if they exist, between negative affect, rejection sensitivity, and separation anxiety that characterizes borderline-, dependent-, and avoidant-like personality disturbance.

As illustrated in Figure 20.10, the dimension of separation distress is portrayed as one of dependency. In interaction with affiliation, the four quadrants can be seen to represent four different social attachment styles frequently described in the literature: (1) *secure* (upper left, where the individual is affectively bonded and not overly distraught with anxiety about losing that bond, and is therefore socially gratified); (2) *ambivalent* (upper right), where the individual is adequately bonded but has intense anxiety about separa-

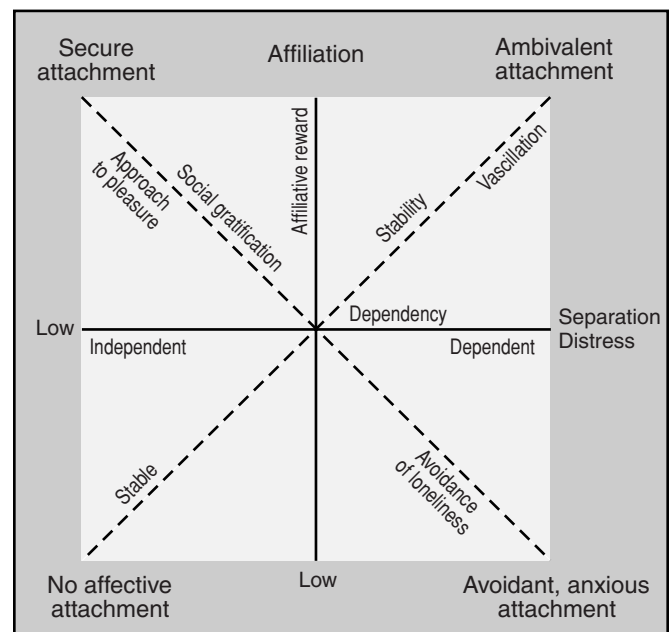

Figure 20.10 Interaction of the higher-order personality traits of affiliation and separation distress. See text for details.

ration from the bond, thereby vacillating between the desire for closeness and protective interpersonal distance. It is in this quadrant that one might expect borderline-, avoidant-, and dependent-like interpersonal disturbance. Moreover, when this quadrant is accompanied by elevation on the higher-order trait of anxiety, the interpersonal disturbance will also be associated with alienation and suspicion of the motives of others, because interpersonal alienation is a strong marker of this trait; Tellegen & Waller, in press; (3) *avoidant-anxious* (lower right, where the individual is not affectively bonded but is anxious about being isolated and alone and thereby avoids loneliness through nonbonded interpersonal relations); and (4) *no affective attachment* (lower left, where there is an absence of affiliative bonding and little anxiety in being separated from social contact, resulting in a stable absence of social attachment that characterizes schizoid-like interpersonal disturbance).

Agentic Extraversion, Anxiety, Aggression, Affiliation × Nonaffective Constraint

A vast body of animal and human evidence consistently associates reduced functioning of 5HT neurotransmission with *behavioral instability*. This instability is manifested as lability, that is, a heightened probability of competing behavioral responses due to a reduced threshold of response elicitation (Spont, 1992). Therefore, instability or lability will increase as a function of increasing stimulus influences on response elicitation of other behavioral systems (Depue & Spont, 1986). This means that the effects of constraint depend on interactions with other personality traits that reflect activity in those behavioral systems. That is, the *qualitative content* of unstable behavior will depend on which neurobehavioral-motivational system, or *affective* personality trait, is being elicited at any point in time (Zald & Depue, 2001), although differential strength of various personality traits will obviously produce relative predominance of particular affective behaviors *within individuals*.

An example of the interaction of neurobiological variables associated with constraint (5HT) and agentic extraversion (DA) helps to illustrate the behavioral instability resulting from low constraint. 5HT is an inhibitory modulator of a host of DA-facilitated behaviors, including the reinforcing properties of psychostimulants, novelty-induced locomotor activity, the acquisition of self-administration of cocaine, and DA utilization in the NAS (Ashby, 1996; Depue & Spont, 1986; Spont, 1992). This modulatory influence arises in large part from the dense dorsal raphe efferents to the VTA and NAS, connections that are known to modulate DA activity (Ashby, 1966; Azmitia & Whitaker-Azmitia, 1997; Spont, 1992). A 5HT-related reduction in the threshold of DA facilitation of

behavior results in an exaggerated response to incentive stimuli, which is most apparent in reward-punishment conflict situations. In such situations, exaggerated responding to incentives results in (1) a greater weighting of immediate versus delayed future rewards; (2) increased reactivity to the reward of safety or relief associated with active avoidance (e.g., suicidal behavior); (3) impulsive behavior, that is, a propensity to respond to reward when withholding or delaying a response may produce a more favorable long-term outcome; and (4) various attempts to experience the increased magnitude and frequency of incentive reward, for example, self-administration of DA-active substances (Babor, Hofmann, & Delboca, 1992; Coccaro & Siever, 1991; Depue & Iacono, 1989; Lesch, 1998). All of these effects impair the ability to sustain long-term goal-directed behavior programs (such as obtaining a college degree) by mental representations of expected rewards that can be repeatedly accessed, held online in the prefrontal cortex, and thereby symbolically motivate behavior (Depue & Collins, 1999; Goldman-Rakic, 1987).

A 5HT-DA interaction is more formally illustrated in the threshold model of behavioral facilitation in Figure 20.7, where 5HT values modulate the probability of DA facilitation (variable X) of incentive behavior across the entire range of incentive stimulus magnitude (Depue & Collins, 1999). This interaction is also modeled in Figure 20.11 within a personality framework, where the affectively unipolar dimension of agentic extraversion (DA facilitation) is seen in interaction with nonaffective

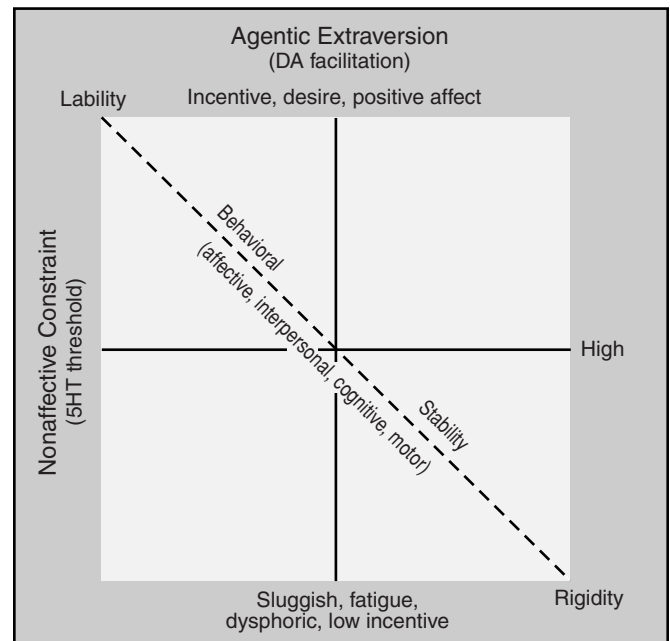

Figure 20.11 Interaction of the higher-order personality traits of agentic extraversion and nonaffective constraint.

constraint (5HT inhibition; Depue, 1996). The interaction of these two traits creates a diagonal dimension of *behavioral stability* that applies equally to affective, cognitive, interpersonal, motor, and incentive processes (Depue & Spont, 1986; Spont, 1992; Zald & Depue, 2001). The diagonal represents the line of greatest variance in stability, ranging from lability in the upper left quadrant of the two-space (low 5HT, high DA) to rigidity in the lower right (high 5HT, low DA).

It is important to note that the extent of lability is affected not only by a 5HT influence, but also by DA's more general facilitatory effects on the flow of neural information, where increased DA activity promotes *switching* between response alternatives (i.e., behavioral flexibility; Depue & Iacono, 1989; Oades, 1985; Spont, 1992). Indeed, when DA transmission is very low, a problem in exceeding the response facilitation threshold occurs, whereas at very high DA transmission levels, a high rate of switching between response alternatives is seen, which can evolve into a low *variety* of responses when abnormally high (e.g., stereotypy; Oades, 1985). Thus, DA's role in switching between response alternatives may explain several of the *nonaffective* manifestations of extraverted behavior, such as rapidity of attentional shifts and cognitive switching between ideas.

This conceptualization of the interaction of 5HT and DA may be relevant to interpersonal behavior. Brothers and Ring (1992) and others (Adolphs, 2003) have argued that humans have an innate cognitive *alphabet* of ethologically significant behavioral signs that signal the emotional intention of others. This alphabet is integrated into its highest representation in human social cognition as a *person* with propensities and dispositions that have valence for the observer, a social construct akin to personality. Personality research has demonstrated that the representation of others exists in two independent, contrasted forms as the *familiar-good other* and the *unfamiliar-evil other*, and the representation of the self is similarly represented in two independent positive and negative forms (Tellegen & Waller, in press). This is consistent with the fact that most percepts and concepts are represented in the brain as separate unified entities (Squire & Kosslyn, 1998). Interestingly, increased DA activation results in a more rapid switching between contrasting percepts, such as two perceptual orientations of the Necker cube or of an ascending-descending staircase (Oades, 1985). Speculatively, we suggest that the frequent, sometimes rapid fluctuation between extreme mental representations of others and/or the self as *good* or *bad* that characterize several forms of personality disorders is related primarily to reduced 5HT functioning (e.g., bor-

derline-like interpersonal disturbance). Furthermore, this condition would be exaggerated when in interaction with increasing DA functioning (e.g., histrionic-like interpersonal disturbance).

As illustrated in Figure 20.12, interaction between constraint-5HT and trait anxiety-CRH dimensions may create a range of anxious phenotypes that vary in their stability, ranging from most highly labile, episodic, and stress-reactive in the upper left quadrant, to chronically anxious with persistent reverberating negative affect that creates an attitudinal hostility in the upper right quadrant (Zald & Depue, 2001). In support of this interaction, Goddard, Charney, and Germine (1995) recently demonstrated in normal subjects that, when combined with a 5HT antagonist, activation by an NE agonist of LC norepinephrine projections (which is activated by stress-induced PGI CRH neurons) resulted in significantly *greater* NE release in the brain and subjective feelings of anxiety, nervousness, and restlessness than when the NE agonist was administered without a 5HT antagonist. Moreover, together with these findings, our model would account for the weak relation (accounting for 3% to 4% of the variance in behavior) between trait anxiety and a genotypic variant of the 5HT uptake transporter, which may lead to reduced 5HT functioning via negative feedback effects on 5HT cells (Lesch, 1998). In this case, reduced 5HT functioning may disinhibit the LC NE activity-induced autonomic arousal thought to contribute to subjective anxiety (Azmitia & Whitaker-Azmitia, 1997).

Figure 20.12 Interaction of the higher-order personality traits of anxiety and nonaffective constraint.

Affective aggression is a goal-oriented pattern of attack behavior that is strongly modulated by incentive motivational processes and is markedly disinhibited by conditions of reduced 5HT functioning (Coccaro & Siever, 1991; Depue & Spont, 1986; Lesch, 1998; Panksepp, 1998; Spont, 1992). This interaction is likely more complex in that behavioral expression of affective aggression is relative to the strength of the separate but tightly linked neurobehavioral system of fear (Panksepp, 1998). Thus, in Figure 20.13, the vertical axis is represented as a ratio of the strength of affective aggression to fear, and this ratio is modulated by constraint-5HT to produce heightened episodic, impulsive aggression in the upper left quadrant and more chronic aggression and attitudinal hostility in the upper right quadrant. The common finding that reduced 5HT functioning is associated with increased affective aggression is thus expressed in Figure 20.13 but is seen as a function of fear as well.

An interaction of 5HT variation with affiliation was discussed earlier, where reduced 5HT functioning creates frequent, rapid fluctuations between extreme mental representations of others as *good* or *bad*. Such unstable evaluations of others greatly impairs interpersonal relations and may be aggravated in individuals with elevated trait anxiety levels (e.g., borderline-like interpersonal impairment). Another effect of reduced 5HT on affiliation was observed by Higley, Mehlman, Taub, and Higley (1992), who demon-

strated that monkeys with low 5HT functioning are overly aggressive and socially rejected by peers. Such monkeys manifest appropriate sociosexual behavior, but its expressive features, in terms of timing and magnitude, appear to be poorly modulated, thereby negatively arousing peers (Higley et al., 1992). It may be that this effect is enhanced in individuals with elevated trait aggression levels.

Conclusions, Implications, and Future Directions

Models of personality traits based on only one neurotransmitter are clearly simplistic and require other modifying factors (Ashby, 1996). In addition, individual differences of psychobiological origin in lower-order traits will represent error variance in predicting higher-order traits from any one variable alone (Livesley, Jang, & Vernon, 1998). Using genetic extraversion as an example, 5HT will certainly not be the only tonic inhibitory modulator of an elicitation threshold. For instance, functional levels of gamma-aminobutyric acid (GABA) tonic inhibitory activity may also influence the threshold of behavioral facilitation as an inhibitor of substance P, a neuromodulator having excitatory effects on VTA DA neurons (Kalivas, Churchill, & Klitenick, 1993; Le Moal & Simon, 1991). Moreover, receptors for GABA, CCK (cholecystokinin), opiates, substance P, and neurotensin are found in the VTA, and their activation can markedly affect DA activity (Kalivas et al., 1993; Le Moal & Simon, 1991). Also, because monoamine oxidase (MAO) is responsible for presynaptic degradation of biogenic amines (DA, 5HT, NE), it may be an important variable in interaction with DA functioning, particularly MAO-B, which predominates in primates and has DA as a specific substrate (Mitra, Mohanakumar, & Ganguly, 1994).

Despite the complexity inherent in the interaction of neurotransmitters in emotional traits, there is good reason to start with one neurotransmitter of substantial effect within the neurobehavioral system underlying a trait, explore the details of its relation to that trait first, and then gradually build complexity by adding additional factors one at a time. This is particularly true of biogenic amines and neuropeptides, because they are phylogenetically old and modulate brain structures associated with behavioral processes relevant to personality, including emotions, motivation, motor propensity, and cognition (Depue & Collins, 1999; Lesch, 1998; Luciana, Collins, & Depue, 1998; Luciana, Depue, Arbisi, & Leon, 1992; Oades, 1985). Furthermore, considering their nonspecific modulatory influence and broad distribution patterns in the brain (Ashby, 1996; Aston-Jones et al., 1996; Oades & Halliday, 1987; Tork, 1990), variation in a single neuromodulator

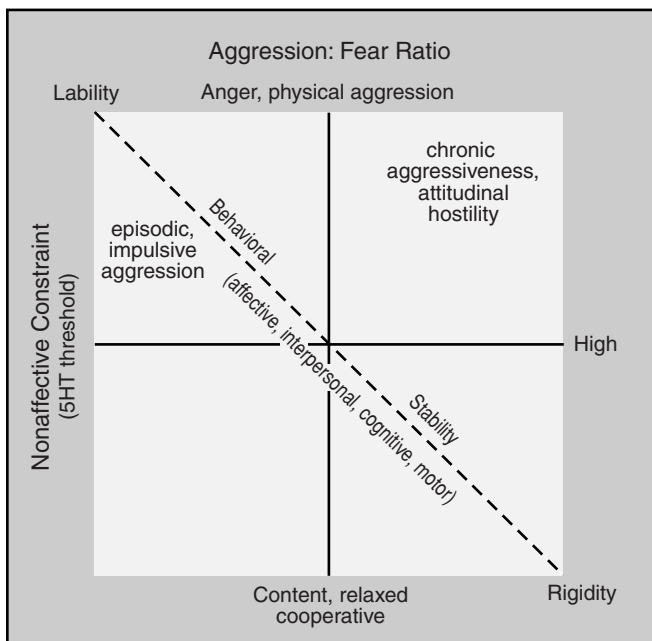

Figure 20.13 Interaction of the higher-order personality traits of anxiety and nonaffective constraint.

can have widespread effects on behavior and on the functioning of multifocal neural networks (Mesulam, 1990), as animal research on the behavioral effects of DA, CRH, μ -opioids, and 5HT has clearly demonstrated. Therefore, variation in biogenic amines and neuropeptides may provide powerful predictors of human behavioral variation. Such neuromodulators may serve as important building blocks for more complex models of personality traits.

Illustration of the interactions of two traits taken at a time, as in this chapter, is informative, but of course underestimates the complexity of reality. The neurobehavioral systems underlying all of the higher-order traits interact. Therefore, we conceive of personality disturbance as *emergent* phenotypes arising from the interaction of the neurobehavioral systems underlying major personality traits.

Our multidimensional model is illustrated in Figure 20.14. In the model, the axes are defined by neurobehavioral systems rather than by traits, because traits are only approximate, fallible estimates of these systems, and trait measures vary in content and underlying constructs. In Figure 20.14, behavioral approach based on positive incentive motivation (underlying agentic extraversion) and anxiety (underlying neuroticism or trait anxiety) are modeled as a ratio of their relative strength, because the opposing nature of their eliciting stimuli affects behavior in a reciprocal manner, such that the *elicitation* or *expression* of one system is influenced by the strength of the other (Gray, 1973). As we discussed, the interaction of these two systems strongly influences the style of an individual's emotional behavior. The affiliative reward dimension (underlying trait affiliation) in the model largely influences the interpersonal domain, whereas the neural constraint dimension (underlying the trait of nonaf-

fective constraint) modulates the expressive features of the other systems. Due to the limitation of graphing more than three dimensions, it should be noted that the model includes two other systems/traits that we suggest influence the manifestation of personality disturbance. As suggested in the section on trait interactions, we believe that a dimension of affective aggression/fear is necessary to account for the full range of antisocial (high aggression/low fear) behavior, and that a dimension of separation anxiety/rejection sensitivity strongly contributes to dependent-, avoidant-, and borderline-like disturbance (all high on this dimension). Taken together, then, the model proposes that the interaction of at least six neurobehavioral systems underlying dimensional personality traits is necessary to account for the emergent phenotypes observed in personality disturbance.

Three significant features of the model are worth emphasizing. First, the phenotypic expression of personality disturbance, represented by the gray-shaded *reaction* surface in the figure (accounting for ~10% of the population; Grant et al., 2004; Lenzenweger et al., 1997; Samuels et al., 2002; Torgersen et al., 2001), is continuous in nature, changing in character gradually but seamlessly across the surface in a manner that reflects the changing product of the multidimensional interactions. It may be that certain areas of the surface are associated with increased probability (risk) of certain features of personality disturbance, and this is represented in the right-back area of the figure as an elevation in the surface that is continuous rather than distinct in contour. Thus, this representation is not meant to imply that a distinct disorder or category exists in that particular area of the surface. Second, the extent and positioning of the reaction surface is weighted most heavily by increasing anxiety, decreasing neural constraint, and decreasing affiliative reward. This weighting is also reflected in the lines with directional arrows overlaying the gray surface in the figure, which illustrate increasing negative emotionality, lability, and interpersonal impairment. These three factors were found to be the most common characteristics of all personality disorders in the meta-analysis of Saulsman and Page (2004), thereby empirically supporting their emphasis in our model. Third, viewing personality disturbance as a *reaction* surface implies that the magnitude of disturbance at any point on the surface is variable, waxing and waning with fluctuations in environmental circumstances, stressors, and interpersonal disruptions both within and across persons over time. Indeed, we recently demonstrated in a longitudinal assessment of the stability of formally defined personality disorders that phenotypic intensity varied markedly over time, thereby affecting the presence/absence of diagnostic status as well as level of symptomatology (Lenzenweger, Johnson, et al., 2004).

Figure 20.14 A multidimensional model of personality disturbance. See text for details.

Implications of the Model

Several implications of the model can be outlined. First, the model may help to explain sex differences in some forms of personality disturbance. The increased prevalence of males with antisocial behavior may reflect the higher mean of males in the population on the trait of aggression/fear and a lower mean on nonaffective constraint (including 5HT functioning; Spont, 1992). Additionally, the increased prevalence of females in clinical populations with borderline- and dependent-like personality disturbance may reflect a combination of (1) their higher mean on both trait anxiety (borderline) and separation distress (dependent); (2) their higher mean on affiliation, thereby increasing the need for social relationships whose loss is feared; (3) their lower mean on agentic extraversion, particularly social dominance, hence enhancing the predominance of high levels of trait anxiety; and (4) their lower mean on aggression/fear, hence decreasing the prevalence of antisocial behavior (Depue & Collins, 1999; Kohnstamm, 1989; Tellegen & Waller, in press).

Second, the model suggests that research on the lines of causal neurobiological influence within the structure of *normal* personality will need to be a primary focus if the neurobiological nature of personality disturbance is to be fully understood. At present, there is a paucity of systematic research in this domain (Depue & Collins, 1999; Depue & Morrone-Strupinsky, in press). Third, the multidimensional nature of the model indicates that univariate biological research in personality disturbance will inadequately discover the neurobiological nature of personality disturbance. Thus, not only is multivariate assessment suggested, but methods of *combinatorial* representation of those multiple variables—as in profile, finite mixture modeling, latent class, discriminant function, and multivariate taxonomic analyses—will need to be more fully integrated in this area of research. Fourth, we propose that this neurobehavioral approach should be found in a multitude of venues, not merely in basic wet-lab investigations, if one wants to fully understand other aspects of personality disturbance at other levels of analysis. For example, in a recent study of the executive neurocognitive processing of individuals with Borderline Personality Disorder (Lenzenweger, Clarkin, Fertuck, & Kernberg, 2004), it was found that the constraint system was strongly associated with executive functioning deficits, whereas positive emotion and negative emotion (anxiety) were not. Moreover, constraint remained predictive of executive functioning deficits even when depression and anxiety, well-known features of Borderline Personality Disorder, were taken into account. These findings were

particularly interesting as the number of borderline features was unrelated to the executive functioning deficits, which highlights the utility of making use of neurobehavioral systems and their indicators as a way of parsing cognitive performance data. Finally, the trend in development of neurotransmitter-specific drugs may not fully complement the pharmacotherapy requirements of personality disturbance. If personality disturbance represents emergent phenotypes of multiple, interacting neurobehavioral systems, then basic research on the pharmacological modulation of neurobehavioral systems and clinical research on multiregiment pharmacotherapy are greatly needed.

APPENDIX: PERSONALITY QUESTIONNAIRE TRAITS USED IN 11 STUDIES THAT CORRESPOND TO THE NUMBERED TRAIT ABBREVIATIONS ILLUSTRATED IN FIGURE 20.5

THE NATURE-NURTURE CULTURE WARS

By and large, investigators and scholars contributing to this second edition of Cicchetti and Cohen's *Developmental Psychopathology*, including the author of this chapter, were academically reared in a scientific generation marked by a confluence of two irreconcilable views of the origins of human disorders. Within a single generation, physicians,

The research and thought on which this chapter is based were supported and funded by the John D. and Catherine T. MacArthur Foundation Research Network on Psychopathology and Development. An earlier version of the chapter was presented at the Millennium Dialogue on Early Child Development sponsored by the Ontario Institute for Studies in Education of the University of Toronto.

clinical and developmental psychologists, social workers, and laboratory investigators were steeped in the twin agendas of environmental and biological determinism. In the former of these views, prominent in the scientific world of the 1960s and 1970s, disease and disorder were held to be products of contextual exposures and adversities. Human afflictions, it was believed, were due almost exclusively to the acute and chronic, cumulative influences of environmental agents of disease. Such agents included psychological stressors, impoverished living conditions, physical toxins, infectious pathogens, and inadequate or malevolent parenting. Prevention and treatment were taken to require alterations in these causative environmental exposures. Thus, Schizophrenia was viewed as the product of psychological "double binds" in dysfunctional family units, Autism was regarded as the legacy of cold, distant mothers,

and maternal overprotectiveness figured prominently in the presumed etiology of childhood anxiety disorders.

In a second canonical view, emerging at the pinnacle of the first by virtue of a revolution in molecular biology, human disorder was thought to be principally the result of biological frailties built into the structure of the heritable genome. Individual genetic differences, occurring on average in 1 of every 1,000 nucleotide base pairs, were seen as likely biological substrates for many human disorders, and quantitative trait loci were thought to constitute the multiple gene systems that, in isolation, code for variation in complex behavioral traits (Plomin & Crabbe, 2000). Most, if not all, disease, it was posited by some, would one day become explicable within the frameworks of evolutionary biology and human genetics, and eagerly anticipated “gene therapies” would transform the treatment and prevention of disordered biology. Thus, Alzheimer’s disease would one day be accounted for by mutations in the gene coding for apolipoprotein E4; a polymorphism in the promoter region of the serotonin transporter gene would eventually elucidate anxiety disorders and phobias; and the long repeat allele of the DRD4 dopamine receptor gene would explain the etiology of Attention-Deficit/Hyperactivity Disorder and other externalizing behavior problems. Within 3 decades’ time, two opposing and mutually exclusive causal orthodoxies captured and held the high ground of scientific discourse on the genesis of human disease.

NEW EVIDENCE FOR BIOLOGY-CONTEXT INTERACTIONS

Vulnerabilities in both positions first became evident as three sets of research findings emerged in the final years of the twentieth century. First, the nascent field of behavioral genetics increasingly documented shared genetic and environmental accounts for variance in the incidence and severity of a broad array of behavioral and psychopathological disorders (Plomin, DeFries, McClearn, & McGuffin, 2001). Using heritability statistics derived from genetically informative research designs, behavioral geneticists became able to decompose phenotypic variance into genetic and environmental components. The genetic component was further subdivided into additive and nonadditive effects, and the environmental component was parsed into shared and nonshared influences (Goldsmith, Gottesman, & Lemery, 1997). While the neuroscience of Schizophrenia provided compelling evidence for a heritable disorder of the brain, epidemiological studies revealed that, even among monozygotic twins, the concordance rate for a diagnosis of Schizophrenia never exceeded 50%. Schizophrenia

was demonstrably a biological disorder with heritable components, but as much as half of the variance in its rate of occurrence was attributable to environmental exposures. The science of behavior and development thus faced a Kierkegaardian dilemma (Kierkegaard, 1843/1986), in which an uncompromising either/or became a more illuminating both/and. Schizophrenia, like virtually all forms of human behavior (Rutter et al., 1997), became understood as a product of *both* biological *and* contextual etiologies.

A second set of findings revealed the previously unsuspected bidirectional influences of biology and context, each on the other. It had become apparent that genes affected both normative and disordered human behavior; now, new evidence indicated the heritability of environmental experience and the potentially profound regulatory effects of social environmental exposures on the transcription of DNA. Discoveries of such bidirectional effects led to a recognition of genotype-environment correlations and to the categorization of such correlations into passive, reactive, and active forms (Plomin, DeFries, & Loehlin, 1977). Studies by Plomin and colleagues demonstrated heritable influences on parental behavior and the home environment (Braungart, Fulker, & Plomin, 1992; O’Connor, Hetherington, Reiss, & Plomin, 1995), and other work showed that even random misfortune, such as stressful events (Kendler, Neale, Kessler, Heath, & Eaves, 1993) and the loss of friends (Bergeman, Plomin, Pederson, McClearn, & Nesselroade, 1990), were partly attributable to genetic variation. Animal research by Meaney and colleagues demonstrated that brief maternal separations among rat pups alter maternal behavior, leading to down-regulation of the corticotropin-releasing hormone (CRH) system and diminished adrenocortical reactivity extending even into adult life (Anisman, Zaharia, Meaney, & Merali, 1998). Other studies in mice found that disruption of social hierarchies led to viral infection-related mortality, which was attributable to an overexpression of genes for cytokine proteins (Sheridan, Stark, Avitsur, & Padgett, 2000), and that caloric restriction prevented aging-related alterations in the expression of genes governing protein metabolism (C.-K. Lee, Klopp, Weindruch, & Prolla, 1999). Although both environmental and biological determinism assumed impenetrable divisions between contexts and genes, new evidence revealed a capacity for the genome to influence environmental experience and for social and physical environments to switch on and off the decoding of genetic material (Cacioppo, Berntson, Sheridan, & McClintock, 2000). Social experience became a heritable predisposition, and the transcription of genes became a process governable by the character of social experience.

The third source of vulnerability in the twin dogmas of biological and environmental determinism was the more recent and accelerating emergence of biology-context interactions in studies of disease etiology. Much of the work examining biological and contextual contributions to pathogenesis was initially preoccupied with partitioning variance into the two distinctive categories of causal factors. Other studies began to illuminate how interplay between biology and context serves a central etiologic role. Mednick, Gabrielli, and Hutchings (1987), for example, found that a child's rearing by an adoptive parent with a criminal conviction did not increase the likelihood of criminality in the child, unless one of the child's biological parents had also been convicted of a crime. Similarly, a polymorphism in the promoter region of the gene encoding CRH has recently been shown to moderate the association between maternal stress and preterm birth (X. Wang et al., 2001). Self-perceived maternal stress was associated overall with pregnancies that were an average of 1.3 weeks shorter, but when a mother possessed a variant allele of the CRH gene, perceived stress was associated with a 2.9-week shortening. A third example is the finding by vanHerwerden et al. (1995) that a polymorphism in the $Fc_{\epsilon}RI-\beta$ gene on chromosome 11q13 alters bronchiolar reactivity to house dust mites and environmental tobacco smoke. While dust mites and smoke are known causes of airway inflammation and allergic symptoms (Palmer & Cookson, 2000), polymorphic markers in this gene are associated with the serum IgE production that is thought to mediate airway reactivity. Explorations of gene-environment interactions are perhaps most robustly developed in the field of environmental toxicology, where as many as 100 candidate genes have been identified with potential for metabolically disposing of carcinogens with known links to lung, brain, and bladder cancers (Albers, 1997). Even in so-called monogenic diseases, such as phenylketonuria, phenotypic expression of the disease is highly variable, suggesting that modifier genes and environmental factors may influence disease severity and course (Scriver & Waters, 1999). Common to each of these examples is a biogenetic vulnerability that amplifies the pathological effects of a social or physical environmental exposure.

Taken together, these three lines of evidence constitute a convincing empirical threat to a monodeterministic view of pathogenesis. Although human morbidities will undoubtedly be identified that have their origins in solely genetic or environmental causes, it appears highly plausible at present to anticipate that variation in the onset and course of *most* human disorders will ultimately be explained by interactions among biological and environmental forces

(Weatherall, 2001). It is now time to move past questions of how much of the variation in outcomes is attributable to genes versus environment and into the more complex and potentially rewarding questions of genetic change and continuity, relations among dimensional symptoms and diagnosable psychopathology, and the interplay between biology and context (Plomin & Crabbe, 2000). As noted by Goldsmith et al. (1997) and Rutter et al. (1997), there is pressing need for broader metaphors of gene-environment interaction, which extend beyond "black box analyses" to hypotheses regarding specific interactive processes.

IMPEDIMENTS TO DISCOVERY

Given the difficulties of discovering biology-context interactions (Wachs & Plomin, 1991), it is all the more remarkable that such interactions are being increasingly identified and characterized in studies of human disease. Gene-environment interactions are assessed as the differential risk effects of an exposure among individuals with different genotypes, or as the differing effects of a genotype among those who are heterogeneous with respect to exposure (Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001). As noted by McClelland and Judd (1993), field studies tend to underestimate the magnitude of interaction effects due to the nonoptimal distributions of the component variables. Interactions accounting for as little as 1% of outcome variance in field research may conceal a true R^2 many times that size that would be found using an optimal, experimental design. When demonstrated, biology-context interactions in human populations may disproportionately exist at the extremes of genetic and environmental variation (McGue & Bouchard, 1998). Animal studies are far more likely to reveal etiologic interactions because of their capacity both for true experimentation and for creating genotypes and exposures that are dimensionally more extreme. Indeed, recent animal work in three different laboratories demonstrated that environments may modify the expression of genotypically derived behavioral differences, even when aspects of context are rigorously controlled (Crabbe, Wahlsten, & Dudek, 1999). Mathematically, analyses of variance and related statistical tests often fail to identify nonadditive effects because they have much less power in tests of interactions than in tests of main effects (Wahlsten, 1990). Newer genetic research designs (Andrieu & Goldstein, 1998), along with statistical approaches that are more sensitive to interaction effects (Kraemer et al., 2001), are now abetting the discovery of complex interactions between and among biologically and environmentally based factors.

SYMPHONIC CAUSATION AND THE INTERACTION OF BIOLOGY AND CONTEXT

What such methods are poised to uncover, it is argued here most centrally, is a kind of *symphonic causation*, a set of lawful regularities in the character and effects of biology-context interplay, which might together compose a foundational principle for understanding the origins of human disease. Our early forays into the territories of etiologic complexity seem to suggest that both necessity and insufficiency are the twin hallmarks of the biological and experiential factors that contribute to disease causation. It may plausibly be the case that few if any human disorders are the products of unilateral pathogenesis and that one of the core features of disease is its essential dependence on a confluence of biologically grounded vulnerabilities and contextually based pathogenic influences. If so, then the causation of human morbidities must be viewed as symphonic, in the sense that their etiologies necessitate a coming together, a conjoining, of diverse, categorically distinctive etiologic elements. Symphonic means “sounding together,” a chordal synthesis by which two or more elemental sounds create, in their confluence, a new presence not derivable from the attributes of its parts. Disease may thus imply a lawful but unanticipated convergence of the interior self, in the form of heritable or acquired biological susceptibilities, with the exterior environment, in the form of pathogenic agents of disease.

It is essential to note that this argument is focused neither on the statistical evaluation of cross-product interaction terms nor on the benefits of multilevel analysis. As noted earlier, there are important mathematical impediments to the detection and characterization of interaction effects, and there is ground to be gained both in statistical approaches to evaluating potential interactions and in research designs that maximize their detection. Nonetheless, more is needed than simply better, more pliable statistical tools. Rather, there is a deeper, more fundamental need for a theory of disease that incorporates observed invariances in the character of biology-context interactions. Similarly, although multilevel analysis (i.e., concurrent measurement at multiple levels of organizational complexity) is a heuristic and often revelatory tool, a different, though complementary strategy is being advanced here. A search for invariances in biology-context interplay may indeed involve scientific analysis at very different levels of organization (e.g., the levels of gene and family environment), but the promise of such a search lies not in its implicit penetration of multiple organizational strata, but in its *binocularity*, that is, the conjoining of individual biol-

ogy and shared context into a unitary image of disease and health.

There are at least two corollaries of such a vision of health and disease. The first is that the preservation of health and the genesis of disease are seen, in such a framework, as two facets of the same phenomenon rather than as distinctive and oppositional biological processes. Historically, for example, medicine and public health have been mutually self-regarded as separable and discontinuous fields, medicine addressing pathogenesis and the curative treatment of diseased individuals and public health expounding prevention and the safeguarding of population health. Adoption of a symphonic causation model, on the other hand, implies a reconciliation of medical and public health perspectives and invokes an explicit recapitulation of the ancient Greek conception of harmonious and disharmonious relations. Disease is the morbid conjunction of individual susceptibility and external threat, and health is a state of harmony that exists between individual and context. Thus, the prevention of disease occurrence is a stewardship of harmony, a preservation of the *symphonic* congruity between the needs and vulnerabilities of the individual and the provisions and perils of the environment.

A second corollary is the potentially nonstochastic character of such confluences of biology and context. If biology is capable of invoking and changing context, and if context is capable of altering the expression of individual biology, then the possibility arises for the production of autocatalytic, self-promoting feedback loops involving biology-context-biology chains of influence. Examples are the findings that adolescents with Conduct Disorder affiliate actively with other conduct-disordered peers (Dishion, Patterson, Stoolmiller, & Skinner, 1991) and that young people with internalizing symptoms show a predisposition to form relationships with others who are similarly affected (Hogue & Steinberg, 1995). An array of multiple alleles predisposing to social anxiety, as another example, may lead to a child's marginalization in early social groups, which may turn on or off the transcription of genes responsible for the regulation of affect, leading to the development of Major Depression. Such chains of influence could arguably account for the highly nonrandom distribution of disease and for the persistence and acceleration of morbidities within a subset of human populations. The most well-replicated finding in all of child and adult health services research is that a small minority of any given population, usually about 15% to 20%, sustains well over half the morbidity in the population and is responsible for the majority of health services utilization (Boyce, 1992;

Starfield et al., 1984). This disproportionate disease burden, borne by a small subpopulation, has been found repeatedly, among the wealthy and the impoverished, for both industrialized and developing societies, in Western as well as Eastern cultures. It appears to be a universal reality that ill health accumulates and multiplies over time in a relatively small group of disproportionately affected individuals. One plausible account for such misfortune is the existence of positive feedback systems in the interplay of biology and context, in which biological susceptibilities invoke new environmental risks, which in turn induce new biological proclivities to disease, and so on.¹ Such failures of homeostatic control might credibly account for a majority of morbidity, disability, and premature mortality in the human populations of the world. If so, a search for invariances in symphonic causation might reasonably lead to new insights into the sources and solutions for the afflictions of twenty-first-century societies.

SENSITIVITY TO CONTEXT: AN EMERGING EXEMPLAR OF BIOLOGY-CONTEXT INTERACTIONS

In the developmental psychobiology laboratory that I lead with my colleague Abbey Alkon at the University of California, Berkeley, a particular form of invariance in the symphonic interaction between biology and context has emerged from our work over the past 10 years. In an effort to illuminate and understand the unevenness in childhood morbidities, we have studied the joint influences of naturally occurring adversities and psychobiological reactivity on biomedical and psychiatric endpoints in 3- to 8-year-old children. Stressors occurring in family, school, and community settings have been used to operationalize contextual adversities, and adrenocortical, autonomic, and immunologic responses to highly standardized laboratory challenges have been assessed to index psychobiological reactivity. A remarkably consistent set of findings, from prospective, quasi-experimental, and experimental research designs, has been revealed, in which highly reactive children evince either unusually high or distinctly low rates of morbidity, depending on the character of the surrounding social environment. This particular lawful regularity in the patterns of biology-context

interactions suggests that biological factors may regulate individual, organismic sensitivity to environmental influence.

Stress and Child Health

The social epidemiological research on which our program of investigation has been built is a broad expanse of findings, reported over 40 years, indicating reliable associations between stressors and health in both children and adults. With stress alternately conceptualized as stressful life events (e.g., T. W. Miller, 1998), chronic adversities (e.g., Kelly, 2000), or the occurrence of a major natural or man-made disaster (e.g., Pynoos, Goenjian, & Steinberg, 1998), cohort studies with strong prospective designs have repeatedly documented unconfounded associations between stressors and health end points, including acute infections (Cohen, 1999), injuries (Boyce, 1996), chronic medical conditions (Boekaerts & Röder, 1999), psychopathological morbidities (Jensen, Richters, Ussery, Bloedau, & Davis, 1991), and health care utilization (Ward & Pratt, 1996). Such evidence has been extended to experimental designs in which exposures to pathogenic agents of disease have been randomly allocated and prior psychological stressors are predictive of disease onset and severity (Cohen, Miller, & Rabin, 2001). Despite the increasing rigor of such studies and the elegance of the more recent research designs, epidemiological findings have consistently indicated that stress-illness associations, though reliable and significant, are universally modest in magnitude, never accounting for more than about 10% of the variance in health outcomes. Such significant but modest associations suggest that contextual stressors may play a predisposing but not sufficient or directly etiologic role in pathogenesis. The findings further suggest that individual susceptibility to stressors may operate as an additional, perhaps interactive, factor in the pathways leading to disease or disorder.

Psychobiologic Reactivity to Environmental Adversity

Originating in studies of risk factors for the development of coronary heart disease in adults, systematic investigation of individual differences in stress reactivity began with protocols examining heart rate and blood pressure changes during the completion of stressful laboratory-based tasks (Matthews, 1986). Broad variability in such reactivity was documented in early studies of adult subjects, and predictive relations were described with incident hypertension and coronary disease (Cacioppo et al.,

¹Conversations with my colleague David Ragland led to a consideration of positive feedback loops in the uneven production of human morbidities.

1998). The work of Matthews and colleagues (Matthews, Woodall, & Allen, 1993; Matthews, Woodall, & Stoney, 1990) extended such research into studies of adolescents and young adults, and Cacioppo, Berntson, and coworkers (Berntson, Cacioppo, Quigley, & Fabro, 1994; Cacioppo et al., 2000) developed new methods for ascertaining not just integrative, downstream physiologic measures such as heart rate and blood pressure, but direct assessments of sympathetic and parasympathetic activation. Adrenocortical responses to laboratory challenges were pursued by Gunnar (1987) and her colleagues using measures of salivary cortisol, and given the known regulatory effects of catecholamines and cortisol on immune targets, other researchers began examining cellular (Manuck, Cohen, Rabin, Muldoon, & Bachen, 1991) and humoral (Cohen et al., 2001) immunologic responses in standardized reactivity paradigms.

In our Berkeley laboratory, a series of studies have been conducted employing adrenocortical, autonomic, and immunologic reactivity to a set of standardized social, cognitive, physical, and emotional challenges completed over a 20- to 30-minute protocol. As reported in detail elsewhere (Alkon et al., 2003; Boyce, Barr, & Zeltzer, 1992), individual differences commensurate with those found in adults have been identified in children's reactivity to stressors. In addition, developmental trends in the magnitude of such reactivity have been noted, and direct associations have been found with behavior problems indicating risk for internalizing and externalizing forms of developmental psychopathology. Children showing high-magnitude reactivity to laboratory stressors appear to be characterized by predispositions to a shy, inhibited behavioral phenotype (Boyce et al., 1992; Kagan, 1994); precocious capacities for delay of gratification (O'Hara & Boyce, 2001); poorer recall of acutely stressful events (Stein & Boyce, 1997); subordinate positions in early social groups (Boyce, 2004); and high risk for affective and anxiety-related behavioral symptoms and low risk for externalizing behaviors (Boyce et al., 2001).

Stress \times Reactivity Interactions

Most pertinent to the interplay of biology and context, however, our studies have nearly invariably found significant interaction effects between indicators of psychobiological reactivity and measures of social environmental adversity (Boyce, 1996; Boyce et al., 1995). As revealed in Figure 21.1, such interactions display a cross-over configuration in which rates of morbidity among low-reactive children are essentially indifferent to the surrounding social context, while rates among high-reactive children are

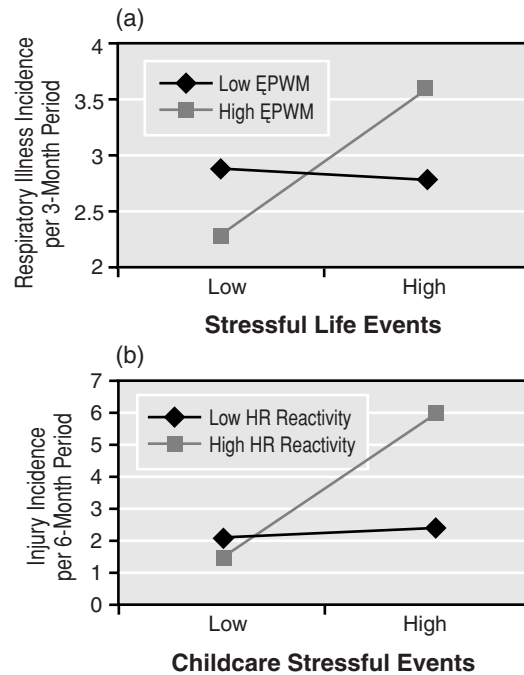

Figure 21.1 Incidences of respiratory illnesses and injuries by level of contextual stress and immunologic (a) pokeweed mitogen response or (b) heart rate reactivity.

highly dependent on contextual effects. Children with low laboratory reactivity have approximately the same incidence of infectious illnesses and injuries in both low- and high-stress settings. By contrast, children with high laboratory reactivity sustain inordinately high rates of illness and injury in stressful settings but inordinately *low* rates in minimally stressful, more nurturant settings.

Although there are several credible accounts for the character of such reactivity \times context interactions, the interpretation we have deemed most plausible is that high reactivity is an index of psychobiological sensitivity to social environmental influence. If autonomic and adrenocortical reactivity reflect heightened susceptibility to the nature of the social environment, then highly reactive children could be expected to sustain more of both the pathogenic effects of stressful, unsupportive social circumstances and the protective, salutary effects of highly supportive and predictable social settings. Highly reactive children would thus be expected to reveal, as they have in each of our studies, the best or the worst of observed health outcomes, depending on the character of the ambient social environment.

Replication and Extension

Of particular importance, neither of the prospective studies whose results were summarized earlier was experimental in

design. Thus, reactive children in low-stress settings were different from the reactive children in high-stress settings; in neither study were the same high- and low-reactivity children exposed to both low- and high-stress contexts. Because of this inherent deficiency in research design, two subsequent studies employed quasi-experimental and experimental designs, in which low- and high-reactive individuals were observed under both stressful and supportive conditions. The first study examined injury rates before, during, and after a crowding stressor in a troop of semi-free-ranging rhesus macaques; the second was a randomized controlled trial of memory for an acute stressful event under supportive and unsupportive conditions.

The first replication was conducted in a troop of 36 macaques living in a 5-acre natural habitat on the grounds of the National Institutes of Health Primate Center in rural Maryland (Boyce, O'Neill-Wagner, Price, Haines, & Suomi, 1998). One year prior to the study, construction on the grounds of the habitat had imposed, for reasons of animal safety, a 6-month period of troop confinement in a small, 1,000-square-foot building. The crowded conditions of the confinement produced severe stress in the troop, and the incidence of violent attacks and injuries escalated fivefold relative to pre- and postconfinement levels. The animals had been previously assessed, in many hours of individual and group observation, for individual differences in levels of biobehavioral reactivity. As has been observed more generally in rhesus monkeys (Suomi, 1997), approximately 15% to 20% of the animals showed a biobehavioral phenotype marked by predispositions to behavioral inhibition and exaggerated psychobiological reactivity to challenge and novelty. Blinded examination of veterinary records revealed the same form of interaction effect noted in the earlier human studies. Low-reactive monkeys showed little if any escalation in injury rates during confinement, whereas highly reactive, inhibited monkeys sustained dramatic increases in injury rates but strikingly lower rates before and after the stressor. Three of the monkeys died in the period during or immediately following the confinement; all three were high in biobehavioral reactivity. Thus, commensurate with observational results from human studies, the high-reactivity individuals sustained unusually low rates of injuries in normative, low-stress conditions but inordinately high rates under conditions of stress.

A remarkably similar result was obtained in a more recent, formally experimental study conducted in our laboratory by postdoctoral fellow Jodi Quas (Quas, Bauer, & Boyce, 2004). In this experiment, a sample of 56 4- to 6-year-old children completed a standardized reactivity pro-

cedure in a laboratory setting, following which a fire alarm was putatively activated by steam during the preparation of hot chocolate with the child (see Stein & Boyce, 1997, for details of the fire alarm paradigm). The fire alarm episode was highly scripted, ensuring that each child experienced the same verbalizations, events, and sequence. During an interim 2-week period following the first laboratory session, the child's psychobiological data were scored and allocated into categories of high and low reactivity; children were then randomized, for the second session, into high and low support conditions, with stratification by reactivity status. High support consisted of a warm, engaging examiner who requested from the child both spontaneous and probed recall of the events surrounding the reactivity testing and the fire alarm episode; in the low support condition, the same examiner was cold and distant in manner. As shown in Figure 21.2, a significant interaction between reactivity and social condition was again detected. Low-reactivity children showed approximately the same level of memory performance under both conditions. High-reactivity subjects, on the other hand, revealed the highest memory performance of the sample under supportive conditions but the lowest recall accuracy in unsupportive conditions. Results of the quasi-experimental study of injuries in rhesus monkeys and the randomized experiment examining memory effects in young children both confirm significant interactions between biology and context and suggest that reactivity to stressors indexes an openness or "permeability" to social environmental effects. Such findings further suggest a form of constancy in the character of biology-context interactions; that is, one recurring pattern in the interplay between individual biology and social context is that *biology controls sensitivity to environmental influence*.

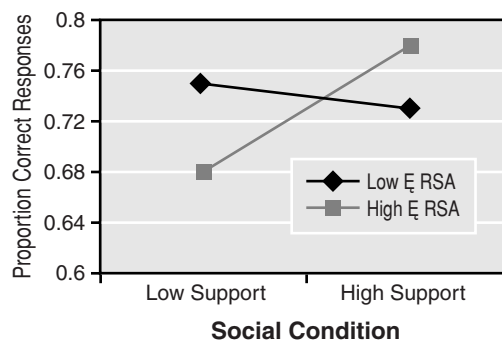

Figure 21.2 Proportion of correct responses on children's memory for stressful event by level of support and autonomic (respiratory sinus arrhythmia) reactivity.

Homologous Findings

Recent reports of gene-environment interactions emanating from the Dunedin Multidisciplinary Health and Development Study (Caspi et al., 2002, 2003), as well as findings on gene \times rearing condition effects in rodents (Meaney, 2001) and macaques (Barr et al., 2003), are suggestive of the same biological sensitivity to environmental influence. As shown in Figure 21.3, for example, taken from the reports of Caspi et al., children with polymorphisms conveying enhanced susceptibility (i.e., low monoamine oxidase A activity and the s/s allele in the promoter region of the serotonin transporter gene) had strikingly higher rates of maladaptive outcomes under

conditions of early adversity (child maltreatment in the case of one analysis, and stressful events in the other). The neurobiological plausibility of these epidemiologic findings has been strengthened by recent evidence linking the short allele of the serotonin transporter gene to hyper-reactivity in the human amygdala (Hariri et al., 2005). Although the augmentation of disordered behavior was the principal, widely heralded findings of the Caspi studies, it is also of note that, in both cases, children with the “risk-augmenting” gene actually had *lower* rates of untoward outcomes when growing up in minimally stressful circumstances. Similarly, the work of Meaney and colleagues demonstrated a diminution in adrenocortical activation to stress among rat pups reared by mothers with more attentive, stimulatory maternal behaviors. However, the *lowest* levels of cortisol reactivity were seen among pups with a genetic, strain-specific predisposition to *high* reactivity cross-fostered to constitutionally attentive mothers (Michael Meaney and Moshe Szyf, personal communication, 24 February, 2005). Finally, the recent studies of Barr (Barr et al., 2003), Suomi, and colleagues at the NIH Laboratory of Comparative Ethology have illuminated interactions between the serotonin transporter polymorphism and rearing conditions, such that infant macaques with the s/s or l/s allele who are peer- rather than mother-reared showed significantly higher levels of violent aggression. What has not been as broadly appreciated is the observation that infants with the same allelic genotype raised by their mother were *lower* in aggression than their mother-reared counterparts with the low-risk l/l allele. This observation provides a possible genetic substrate for Suomi’s (1991) earlier observation that infant macaques with a “vulnerable” biobehavioral phenotype flourish developmentally when cross-fostered to the care of the troop’s most nurturing adult pair.

Taken together, these findings suggest, as indicated earlier in the work of Boyce and colleagues, that the same genotypic variation conferring developmental risk in settings of maltreatment and stress may actually serve protective functions in rearing environments characterized by support, predictability, and care. Such bivalent, context-dependent influences of specific polymorphisms suggest that they operate not as risk factors, but as regulators of environmental *sensitivity*, enhancing susceptibility to both pathogenic and protective aspects of environmental conditions (Boyce & Ellis, 2005; Ellis, Essex, & Boyce, 2005). This bidirectionality in the effects of genotypic variation may also offer a partial account for the paradoxical observation that “risky genes” have been substantially conserved over the evolutionary history of the species involved.

SYMPHONIC CAUSATION: A PROVISIONAL NOSOLOGY OF BIOCONTEXTUAL INTERPLAY

What then are the implications of adopting a symphonic or interactive frame of reference in the study of developmental psychopathology and its origins? Such a view demands, first, a new exploration of *how* biology and context work together to initiate and sustain pathogenesis or to preserve health and well-being. A starting point is a consideration of the nosological or taxonomic regularities in biology-context interactions.

The Need for a Nosological Framework

The existence and importance of biology-context interactions in the genesis of human morbidities have become—finally and rightfully—an article of faith. A recent report from the National Academy of Science's Institute of Human Development said it especially well: "It is time for a new appreciation of the coactivity of nature and nurture in development. Beginning at the moment of conception, hereditary potential unfolds in concert with the environment. The dynamic interplay between gene action and environmental processes continues throughout life" (Shonkoff & Phillips, 2000, p. 39).

Beyond this new canon of interactionism, however, there is a need for more systematic research and reflection on *regularities* in the character of biology-context interactions. It is the observation of such regularities that will begin to reveal deeper truths about *how* genes and environments codetermine human outcomes and *how* individual susceptibility and resilience are conjoined with contextual threat and protection to traverse the severe discontinuity between health and disease. A symphonic view of disease causation would not only acknowledge the bipartite contributions of biology and context, but would begin to codify the systematic congruities in their interactions.

The concept of a symphonic causation of disease, within a nascent philosophy of medicine, bears much in common with Percy's (1989) view of the triadic character of human language. In the same manner in which a conjunction of self and environment produces the experienced *Welt* or world, the confluence of individual biology and environmental peril produces affliction and disease. Pathogenesis and prevention are thus intrinsically triadic; it is out of a symphonic fusion of individual biology and contextual influence that the possibilities for health and disease arise. Among the implications of such a view is a realliance with ancient Platonic and Hippocratic conceptions of health as a harmonious balance between self and society. Thus, the Hippocratic Cor-

pus summarized a view of health as "the expression of a harmonious balance between the various components of man's nature (the four humors that control all of human activities) and the environment and ways of life" (cited in Dubos, 1965, p. 322). Even the pre-Socratic philosopher Alcmaeon of Croton noted the interactive nature of "internal" and "external" causes:

Disease occurs sometimes from an internal cause such as excess of heat or cold, sometimes from an external cause such as excess or deficiency of food. It may occur in a certain part, such as blood, marrow, or brain; but these parts also are sometimes affected by external causes, such as certain waters, or a particular site, or fatigue, or constraint, or similar reasons. Health is the harmonious mixture of the qualities. (translated by G. Miller, 1962)

Within such a rubric, health and disease are seen as the integrative product of the fit or concordance between individual biological proclivities and dimensions of environmental threat and support. What is now needed is a nosological framework that assembles and classifies observable invariances in the operation of symphonic causation.

A Provisional Nosology

Such a provisional nosology of biology-context interactions is presented in Table 21.1, along with exemplars of each category of interactive association. This five-part nosology makes no claim to comprehensiveness in its description of such interactions, and indeed, emerging research blending assessments of both genetic and environmental risk will almost certainly reveal new varieties of interaction. There is also no implication, in the ordering of categories, that one form predominates over another. Rather, this provisional nosological framework is offered as a first effort to aggregate and order emerging observations of biology-context interactions. As such, the nosology is an attempt to advance the same project begun by Lewontin in a 1974 paper on the analysis of causes, by Meehl in a 1977 exposition on specific etiology and strong influence, and by Kendler and Eaves in their 1986 paper on models for joint effects of genotype and environment. Particular but not exclusive attention has been paid here to interactions predicting developmental psychopathology.

Five forms of biology-context interaction are proposed. First, *potentiation* describes individual biology's amplification of the pathogenicity of contextual forces. Because each category describes a form of interaction, such potentiation implies statistical nonadditivity of effects and a situ-

TABLE 21.1 Observed Regularities and Examples

Observed Regularities	Examples
1. <i>Potentiation</i> : Biology amplifies the pathogenicity of context. ^a	<p>Polymorphisms in the genes coding for monoamine oxidase A and the serotonin transporter magnify the pathogenic effects of early maltreatment and stressful events on psychiatric end points (Caspi et al., 2002, 2003). A child's rearing by an adoptive parent with a criminal conviction does not increase the likelihood of criminality in the child, unless one of the child's biological parents has also been convicted of a crime (Bohman, 1996; Mednick et al., 1987).</p> <p>Type I alcoholism (relatively mild abuse, minimal criminality) requires both genetic risk and a risk-promoting childhood environment for expression (Cloninger et al., 1981).</p> <p>Negative environments in adoptive homes have especially harmful effects on adolescent adoptees with antisocial biological parents (Cadoret et al., 1995).</p> <p>Positive family history exaggerates adverse effects of smoking on coronary heart disease incidences (R. R. Williams et al., 2000).</p> <p>Only children with the A1+ allele of the D2 dopamine receptor gene (DRD2) show declines in cognitive abilities related to family stress (Berman & Noble, 1997).</p> <p>Stressful life events are associated with a nearly eightfold increase in risk of autoimmune hyperthyroidism, but only in women (Yoshiuchi et al., 1998).</p> <p>Amphetamines increase dominant behavior in high-ranking male rhesus macaques but increase subordinate behavior in low-ranking monkeys (Haber & Barchas, 1983).</p>
2. <i>Protection</i> : Biology amplifies the protectiveness of context.	<p>High alcohol consumption protects against coronary heart disease by increasing HDL cholesterol, but only in those with a polymorphism on a lipid metabolism (CETP) gene (Corbex et al., 2000).</p> <p>Supportive female audiences lowered blood pressure reactivity to a speech-making task among both males and females, but supportive male audiences diminished reactivity in neither (Glynn et al., 1999).</p> <p>Handling induces enhancements of maternal licking and grooming diminishes adrenocortical and behavioral responses to stress in infant mice, especially among animals in the BALB/c strain (Meaney, 2001).</p>
3. <i>Sensitization</i> : Biology controls sensitivity to context.	<p>Autonomic reactivity to stress is associated with higher incidence of illness and injury in high-stress contexts but lower incidence in low-stress, supportive contexts (Boyce, 1996; Boyce et al., 1995, 1998; J. A. Quas, Murowchick, Bensadoun, & Boyce, 2002).</p> <p>Adoptees with schizophrenic mothers show high rates of disordered thought when placed in communication-deviant families but unusually low rates when placed in effectively communicating families (Wahlberg et al., 1997).</p> <p>Highly reactive infant macaques are marginalized and developmentally slow when raised in normative conditions, but when cross-fostered to caring adult pairs, become developmentally precocious, emigrate early from the natal troop, and assume dominant positions in the adult hierarchy (Suomi, 1997).</p> <p>Adult female adoptees of alcoholic biological parents have an increased risk of Major Depression when placed in homes with a psychiatrically disturbed adoptive parent, but a lower risk of depression than even subjects with no alcoholic biological parents when placed with psychiatrically healthy adoptive parents (Cadoret et al., 1996).</p>
4. <i>Specification</i> : Biology selects the symptomatic expression of contextual pathogenesis.	<p>Relatives of patients with early-onset depression are more likely to be depressed if they are female and more likely to be antisocial if they are male (Winokur et al., 1971).</p> <p>Expressed emotion in the family environment is demonstrably related to the relapse of affective disorders, eating disorders, and Schizophrenia, each of which appears to have its own specific biological substrate (Butzlaff & Hooley, 1998).</p> <p>Benzene exposure is associated with both hemotoxicity and shortened gestation, but each outcome is moderated by distinctive genetic polymorphisms (Lan et al., 2004; X. Wang et al., 2000).</p> <p>(Reverse specification) The short-repeat allele of the serotonin transporter polymorphism confers increased risk of depression on exposure to stressful life events (Caspi et al., 2003) but appears protective against the environmental exposures associated with sudden infant death syndrome (Hunt, 2005).</p>
5. <i>Facilitation</i> : Biology controls exposures to contextual pathogenicity.	<p>Genes controlling the melanization of skin determine predispositions to experiences of adversity and racism in North America and other regions of the world (D. R. Williams, 1997).</p> <p>Serotonin transporter gene polymorphisms, which systematically differ among Indian and Chinese hybrid rhesus macaque lineages, are associated with aggressive and risk-taking behavior and may account for selective emigration over the Himalyan Mountains in the early history of the species (Champoux et al., 1997; Heinz et al., 1998; S. J. Suomi, personal communication, November 22, 2003).</p> <p>Carriers of the gene for excessive iron absorption (HFE) are at risk for hemochromatosis (Cogswell et al., 1998).</p>

^aIt is important to note that the linguistic construction of the five interaction categories is not meant to imply that biological factors are the active component of the interaction, exerting various forms of influence on a set of more passive contextual features. Rather, category descriptions simply adopt the convention of naming biology first and context second, with the understanding that they could be stated in reverse and that examples of opposite effects are abundant.

ation in which individual biology affects the direction or strength of the relation between environmental factors and child outcomes (Baron & Kenny, 1986; Kraemer et al., 2001). A second form of interaction is *protection*, that is, that in which biology amplifies the protectiveness or salutogenic aspects of context. Again, nonadditivity is implied, but the effect of biology is to augment the essentially preventive character of the environmental factor. Third, *sensitization* is the capacity of biological factors to control susceptibility or permeability to environmental influence. This is the form most closely defining the character of psychobiological reactivity \times social environmental adversity interactions, which were summarized in the prior section. Fourth, *specification* suggests that biology is capable of selecting the particular symptomatic expression of contextual pathogenesis. This is the interpretation of interaction promulgated by Steinberg and Avenevoli (2000) in their paper noting the tendency for environmental risk to exert generic effects and biological susceptibility to narrow the range of possible disordered outcomes. Finally, a fifth form of interaction, *facilitation*, is that in which biology controls exposures to contextual pathogenicity. Here, the role of individual biology is not one of altering the amplitude of environmental effects, but rather one of determining the presence or degree of exposure to pathogenic or protective contextual elements.

Ottman (1996) has also proposed a five-model nosology of gene-environment interactions, which bears little commonality with the categories presented here. Rather, her models constitute four possible combinations of genotype and exposure in terms of their individual effects on disease risk, along with a noninteractive model in which the genotype increases the production of a nongenetic risk factor (e.g., phenylketonuria). The impetus for the formulation of Ottman's system, however, was entirely commensurate with that motivating the present discussion, that is, the evident need for an interim taxonomy under which categories of interaction could be usefully and perhaps heuristically organized.

Ottman's (1996) nosology also lucidly emphasizes a point important to both categorical systems, that is, the reciprocity between biological and contextual perspectives in describing a given interaction. In defining the character of interaction categories, each has been described in terms of biology's influence on the magnitude, direction, or expression of contextual effects. This convention serves to standardize the format of the nosological categories, but it implies no precedence of biology over context, or the reverse, and each class of interaction can be interchangeably characterized in terms of contextual modification of biolog-

ical effects. Thus, it is in the nature of biology-context interactions that "Biology amplifies the pathogenicity of context" can be reciprocally interpreted as "Context amplifies the pathogenicity of biology." In Wallen's (1996) description of sex differences in rhesus monkey behavior, for example, the interaction of prenatal hormones and social contexts could alternatively, and with equal accuracy, be described either in terms of hormonal influences on sex-specific social rearing effects or as social environmental shaping of prenatal hormonal effects. In the section that follows, specific exemplars of biology-context interplay are explored and examples in each interaction category are presented.

Examples of Biology-Context Interplay

A 1996 lecture by Robert Hinde (1998) offered an elegant model of the complexity inherent in interactions among environment, behavior, and biological state in a vertebrate animal species. For the timing of nest completion to coincide precisely with the laying of eggs, the female canary engages in an elaborately unfolding dialogue among multiple interactive factors, including the physical environment of the nest, reproductive endocrine activity, and maternal behavior. Contextual factors acting on the hypothalamic-pituitary-adrenal system result in gonad development and estrogen release, leading to a heightened responsiveness to the male's courtship behaviors. Changes in hormonal state, in interaction with day length and exposures to the male's song, also induce the construction of a nest and the development of a brood patch, a tactilely sensitive area on the female's ventral surface that loses its feathers and develops increasing vascularity. Stimulation of the brood patch by the physical components of the nest successively initiate alterations in nest-building material from grasses to feathers, a diminution in nest-building behaviors, and, finally, further reproductive development of the mother bird. In an exquisite, sequentially rendered interaction among biology, context, and behavior, the nest's construction is completed just as the eggs are ready to be laid.

Biology-context interactions in human and nonhuman primate species are, at present, in a far more primitive state of elucidation than that portrayed by Hinde, but not surprisingly, early glimpses into the character of such interactions are revealing a picture of equally elegant and exacting complexity. For each of the five categories of interaction—potentiation, protection, sensitization, specification, and facilitation—examples are rapidly accruing in both experimental studies of laboratory animals and observational studies of human subjects. Table 21.1 provides a sampler of such interactions.

The first nosological category, potentiation, is a more general version of the diathesis-stress model of developmental psychopathology (Rosenthal, 1970). In this interactive model, biologically grounded susceptibilities accentuate or amplify the inherent pathogenicity of a given contextual exposure. In addition to the previously noted amplifications of risk for psychopathology by neurotransmitter polymorphisms and criminality among biological parents, studies by Cloninger (Cloninger, Bohman, & Sigvardsson, 1981) and Cadoret (Cadoret, Yates, Troughton, Woodworth, & Stewart, 1995) have documented the interactive roles of genetics and developmental environments in accelerating children's risk for alcoholism and drug dependency. Similarly, a positive family history of coronary heart disease has been shown to augment cardiovascular risk associated with smoking (R. R. Williams, Hopkins, Wu, & Hunt, 2000), and a particular allele of the dopamine receptor gene is known to potentiate cognitive decline in children experiencing severe family stress and adversity (Berman & Noble, 1997). Other examples include the effect of female sex on the link between psychological stressors and autoimmune thyroiditis (Yoshiuchi et al., 1998) and the amplification of dominance/subordination behaviors in specific social settings by the administration of amphetamines to rhesus macaques (Haber & Barchas, 1983).

The second form of interaction, protection, involves a biological amplification of a protective environmental factor. For example, the gene encoding cholesteryl ester transfer protein (CETP) plays a key role in lipid metabolism. CETP decreases the concentration of protective HDL cholesterol, and patients with a deleterious mutation in the CETP gene have abnormally high HDL cholesterol. HDL cholesterol has also been shown to increase with alcohol consumption due to reduced activity of CETP, but this is only the case among individuals with certain CETP polymorphisms (Corbex et al., 2000). Another example is the differential influences of gender on both the protective effects of social support (House, Landis, & Umberson, 1988) and the capacity for provision of such support. In one recent study by Glynn, Christenfeld, and Gerin (1999), blood pressure reactivity to a stress-inducing speech-making task was significantly down-regulated, in both men and women, by the presence of a supportive female audience, but no such effects were found for supportive male audiences. The authors conclude that the sex of supportive companions plays a key role in determining the utility and efficacy of the support provided. Finally, as previously noted, the work of Meaney (2001) and colleagues revealed that handling-induced enhancements of maternal licking and grooming reduced lifelong adrenocortical and behavioral responses to

stress in infant mice. This protective effect was particularly evident in the BALB/c strain.

Sensitization, the third category of biology-context interaction, represents an amalgam of potentiation and protection, except that the same biological factor is capable, through an increased sensitivity or permeability to the environment, of alternately raising or lowering risk. Such interactions are evident in the studies of Boyce and colleagues, reviewed earlier, on autonomic reactivity as an indicator of susceptibility to positive and negative environmental conditions of early childhood. Strikingly similar findings have been published by Wahlberg et al. (1997), who demonstrated inordinately high or low rates of schizophreniform thought among the adopted children of schizophrenic mothers, depending on the level of disordered family communication, and Cadoret et al. (1996), who found exceptionally high or exceptionally low rates of depression in adoptees of alcoholic biological parents, depending on the psychiatric health of the adoptive parents. Finally, Stephen Suomi (1987) presented cross-fostering studies among rhesus monkey infants showing that highly reactive infant macaques, when placed in the care of maximally nurturant adult monkeys, evince a dramatic reversal of developmental course, rising to the top of the dominance hierarchy in the adult troop, becoming developmentally precocious, and, if male, being among the first to emigrate out of the natal troop. Evidence for sensitization interactions suggest that biological, perhaps genetic, factors can calibrate the organism's susceptibility not only to health-diminishing adversities, but also to aspects of health-preserving social supports.

Specification is the fourth form of biology-context interaction. In this form, environmental exposures raise generic, global risk for disorder, and biological or genetic factors focus that risk on specific forms of morbidity. Context thus produces undifferentiated liability, and biology narrows the liability to particular somatic, emotional, or behavioral categories. An example is the study of Winokur and colleagues (Winokur, Cadoret, Dorzab, & Baker, 1971) showing that the relatives of individuals with early-onset major depression were more likely to develop psychopathology and that the form of disorder was more likely to be depression among females and antisocial behavior among males. Thus, common family environments produced an elevated risk for mental disorder, but the form of disorder was determined by the sex of the individual. In a second example, Butzlaff and Hooley (1998) showed, in a meta-analysis, that expressed emotion in the family environment is associated with relapse in affective disorders, eating disorders, and Schizophrenia, but that each form of disorder had its particular biological sub-

strate. Finally, benzene exposure is associated with both hemotoxicity and shortened gestation in humans, but the exposure effects are moderated by two distinctive sets of genetic polymorphisms: genetic variants in metabolizing enzymes in the case of hematological effects and by susceptibility genes CYP1A1 and GSTT1 in reproductive outcomes (Lan et al., 2004; X. Wang et al., 2000).

An example of *reverse* specification is found in the short repeat allele of the serotonin transporter gene. As noted earlier, work by Caspi and colleagues (2003) has demonstrated an elevated risk of depressive symptoms among individuals with one or two copies of the short allele and who also sustain numerous stressful life events. On the other hand, the short repeat allele appears to be protective for sudden infant death syndrome (SIDS), with the long repeat polymorphism overrepresented and the short repeat underrepresented among SIDS victims (Hunt, 2005). The serotonin transporter polymorphism likely interacts with one or more environmental SIDS risk factors, such as smoking, low socioeconomic status, or prone sleeping. Here, a single genetic polymorphism produces up- or down-regulation of risk for two different disorders depending on exposures to environmental and perhaps other contributing factors.

The fifth and final pattern of interaction in this provisional nosology is facilitation, in which biology implements or controls exposures to contextual exposures. Perhaps the most persistent and tragic example of this interactive regularity is the manner in which genes regulating the melanization of skin determine the likelihood of an individual's chronic exposure to social adversities in North American society (D. R. Williams, 1997). Another example is the possible role of serotonin transporter gene polymorphisms in the presumed selective emigration of rhesus macaques across the Himalayas into China (Champoux, Higley, & Suomi, 1997; Heinz et al., 1998; S. J. Suomi, personal communication, 22 November, 2003). Relative to Indian-derived monkeys, Chinese-hybrid macaques show behavioral predispositions to aggression and novelty, lower cerebrospinal fluid levels of 5-HIAA (a metabolite of serotonin), and a higher prevalence of the long repeat allele of the serotonin transporter gene, an example of genotypic variation biasing physical and social environment-based exposures. Finally, a mutation in the iron absorption gene HFE facilitates the development of the disease hemochromatosis by increasing iron absorption in the gut, leading to iron overload and multiorgan dysfunction (Cogswell et al., 1998). Genes and biology may thus interact with environmental agents and pathogens by fostering or facilitating an individual's exposure to such agents.

Molecular Epigenomic Substrates of Symphonic Causation

To whatever extent these nosologic categories of biology \times context interactions are validated by future scientific observations, such interactions will be linked in specific and definable ways to underlying molecular processes involving DNA transcription, replication, recombination, and repair, as well as RNA translation and the actions of its protein products. It is also not unreasonable to predict that the character of the interactions described epidemiologically (i.e., their instantiation of potentiating, protecting, sensitizing, specifying, and facilitating interactive processes) will be partially mirrored by cellular events describing the interplay between genomic elements and environmentally activated molecular signals.² Although research to date has focused principally on structural variation in DNA sequences, complexities in the regulation of gene *expression* are dramatically expanding the known repertoire of means by which biological and contextual information can interactively operate. Although the control of gene expression can occur via multiple processes affecting DNA transcription/RNA translation (Villard, 2004), three such processes are highlighted here.

First, the initiation of DNA transcription requires the recruitment of RNA polymerase to the promoter region of the gene in question, in close collaboration with a battery of protein *transcription factors*. Internal and external signals—such as developmental events, stressors, or social interactions—are capable of altering the binding of transcription factors to the gene's promoter region, thereby changing the rate of gene expression (Lemon & Tjian, 2000). Each gene has both template and regulatory functions—corresponding to the exon and promoter regions of a given gene sequence—and exposures in social and physical contexts can up- or down-regulate the production of messenger RNA products by changing the availability of transcription factors. An example is the production of c-Fos, an immediate early gene transcription factor, following exposure to an anxiogenic stressor; examining c-Fos expression in high- and low-novelty-seeking rats, significantly lower levels in the CA1 region of the hippocampus have been found among novelty-seeking animals (Kabbaj & Akil,

²It is acknowledged here that, although molecular genetics form the boundary conditions by which gene \times environment interactions take place (Polanyi, 1968), full accounts of such interactions will involve dynamic, irreducible complexities not subsumed by molecular processes, however elegantly defined (Strohman, 2002).

2001). Large-scale, high-throughput DNA microarray technology now allows the identification of patterns of multiple gene expression, changes in such patterns over time or following an exposure, and differences in gene expression profiles among different tissues and individuals. Of greatest relevance to the argument presented here, however, transcription factors can function as either activators or repressors, which accelerate or diminish gene transcription. Transcription factors could thus serve as one molecular genetic substrate for the potentiating or protecting categories of biology \times context interactions.

A second set of gene regulatory processes involves the *epigenome*, that is, the chromatin polymer of histone and nonhistone proteins into which genomic DNA is folded and bundled as nucleosomes, which in turn are packaged within chromosomes. Inside this chromatin matrix there exist variable degrees of physical exposure of the DNA to the molecular machinery of transcription (i.e., RNA polymerase, transcription factors). DNA exposure is modified by methylation of cytosine in CG dinucleotide sequences and by acetylation of histone proteins. Methylation and acetylation patterns can thus govern chromatin structure, thereby influencing gene expression. Complex maternal behavior among mother rats, for example, has been shown to calibrate infant stress reactivity by altering histone acetylation and transcription factor binding to the promoter region of a gene coding for the glucocorticoid receptor (Weaver et al., 2004).

A third source of gene regulation is the existence of polygenic networks in which synthetic interactions occur among complex arrays of the genes implicated in a given disorder. A primary mutation involved in cystic fibrosis, for example, produces defective regulation of the transmembrane chloride channel, but the altered gene's expression is also modified by several other polymorphic sites or gene products (Badano & Katsanis, 2002). In another example, digenic mutations in the ROM1 and RDS genes are silent in isolation, but together produce retinitis pigmentosa (Kajiwara, Berson, & Dryja, 1994). In recent work systematically examining the synthetic lethality of mutant gene pairs in yeast, Tong et al. (2004) found an average of 34 digenic interactions among the 143 mutant genes tested, an extraordinary scope of interactive genetic complexity. Gene networks of equal or greater complexity are anticipated in the developmental programs of mammalian organ systems (Sampogna & Nigam, 2004).

Taken together, these categories of symphonic interaction at the molecular genetic level trace a perimeter of means by which biology and context act together in disease

pathogenesis and the preservation of health. Although there are both experimental and statistical obstacles to the discovery of such interactions, researchers are progressively assembling a repository of examples, which collectively present an early but informative picture of how genes and environments might work together in etiologic processes. That picture, coming gradually into view, tells a story with vast and immediate implications for the future of health care, biomedical research, and public health policy.

CONCLUSIONS AND FUTURE DIRECTIONS

What conclusions can be reasonably drawn from these observations and what implications for psychiatric care, new research, and mental health policy might be derived from a symphonic interpretation of causal processes?

Implications: Care, Research, and Policy

The implications of biology-context interactions for the future of human health are legion. Advances in our capacity for sampling, analyzing, and employing genetic material in research and practice will arguably revolutionize not only the science of human biology, but also the science of human behavior and development. The capacity for assessing multiple genes using microarray patterns of DNA or RNA sequences will alter fundamentally the ease and practicality of ascertaining human genotypes (P. S. Lee & Lee, 2000). DNA sequence variations comprising single-nucleotide polymorphisms (SNPs), which occur once every 1,000 base pairs between two individuals picked at random, will offer the genetic means of fingerprinting genotypic variation that forms the most basic biological substrate of disease (Evans, Muir, Blackwood, & Porteous, 2001). The dbSNP database, for example, now comprises nearly 9 million SNPs; the HapMap project plans to coalesce information on approximately 300 million human genotypes; and the National Institutes of Health has requested proposals to extend such genotyping to an additional 600 million genomes (Hirschhorn & Daly, 2005). These advances in ascertaining and cataloguing human genetic variation offer the means of fulfilling what Bronfenbrenner and Ceci (1994) have proposed as the need to study proximal processes of organism-environment interaction in order to understand the development of phenotypes. As noted by Reiss (Reiss, Plomin, & Hetherington, 1991), this new genomic knowledge will advance understanding not only of biogenetic pathogenesis, but of human contexts and social environments as well. As

researchers become increasingly capable of taking genetic variation into account, the roles of social and physical contextual factors in disease will be discernible with unprecedented clarity. Although much has been achieved by studying social processes in their own right, eliminating the noise of biological variation will produce a level of resolution and focus in studying social contexts never previously attained or even imagined. In our collective scientific pursuit of such precision, however, important methodological, bioethical, and strategic dilemmas arise.

Dilemmas in Computational Biology

First, technological breakthroughs in the ascertainment of genetic variation will facilitate (and are already facilitating) new understandings of biology-context interactions. Much of the difficulty in discovering and analyzing such interactions has been related to the imprecision inherent in using multiple determined, downstream biological measures that are only distantly reflective of the genes and gene expression that are their sources. The ability to assess directly DNA polymorphisms and variable patterns of gene expression not only will allow greater accuracy in the characterization of genetic and epigenetic variation, but will also expedite the choice of more extreme genotypic representation in research designs such as case-control studies.

Along with greater accuracy and efficiency in the measurement of such variation, however, the development of high-throughput data acquisition in the genetic sciences has been accompanied by formidable statistical challenges involving full genome surveys of thousands of SNPs. As reviewed by Hirschhorn and Daly (2005), the sequencing of the human genome, the development of public “libraries” of SNPs, and the dramatic advances in genotyping technology have all contributed to an emerging capacity for detecting disease-linked genetic variation in human populations.

One of the challenges implicit in this capacity for generating unprecedented volumes of genetic information, however, is the choice of *research designs* for ascertaining associations between genetic variation and human disorders. Broadly considered, research approaches for identifying polymorphisms contributing to the prevalent human diseases can be grouped into two broad categories. Candidate gene studies—the approach that has provided most of the knowledge available to date—are those in which genes are selected for assessment based either on their chromosomal location in a region of known linkage to the index disorder or on knowledge of functional characteristics that could influence disease risk. The previously cited work

linking the short repeat allele of the serotonin transporter gene promoter to affective mental disorders, alcohol abuse, and other dependencies are examples of candidate gene studies, in which the 5-HTT promoter was targeted because of known functional linkages between serotonin circuitry and mental health (Barr et al., 2004; Caspi et al., 2003; Kremer et al., 2005). The second, theoretically plausible form of research linking genetic variation to disease is genome-wide association studies, which would survey polymorphic variation across the genome in very large, multiple samples of affected and unaffected individuals. As summarized by W. Y. Wang et al. (W. Y. Wang, Barratt, Clayton, & Todd, 2005), genome-wide study designs remain technically unfeasible at present, though partial surveys of the genome have become possible through the genotyping of many common SNPs in genome-wide association studies. The past 3 decades of genetic research have identified approximately 50 genes and their allelic variants that appear reliably associated with multifactorial human diseases, but it is estimated that as many as 30% of the common disease-associated variants remain undetected, and there are likely hundreds of genetic loci that alter susceptibility to a specific disorder (W. Y. Wang et al., 2005).

The *biometric and computational challenges* of genome-wide studies are also formidable indeed. The statistical power of a study to discover SNPs conferring risk or protection in a given human disorder depends on an array of factors, including the allelic spectrum or architecture of a disease, that is, the number of relevant variants that exist, their allele frequencies, and the potency of their effects on incidence. A review of quantitative trait loci (genetic loci that contribute to variation in continuous phenotypes, such as height), for example, revealed that about half of the candidate causal variants had allele frequencies greater than 5%, whereas the other half had lower prevalences. Further, it is unknown whether the effect sizes of established disease-susceptibility polymorphisms are representative of those yet to be discovered, but the current list bears allelic odds ratios for incident disease in the range of 1.1 to 1.5, that is, relatively small effect sizes that contribute negligibly to familial risks (Risch & Merikangas, 1996).

Partly as a result of these multiple, small contributions of individual SNPs to overall disease risk, genetic investigators and their biostatistical colleagues have increasingly had to contend with the informational tsunamis that result from thousands of genes being screened in samples of thousands of individuals. Extensible, open-source biometric software for use in computational biology and genetics has begun to be made available to the scientific community as

an aid to data acquisition, management, and transformation within genetic and bioinformatic applications (Gentleman et al., 2004). Other sophisticated statistical approaches are in development for *in vitro* studies of dynamic, regulatory networks, such as those involving transcription factor regulation of gene expression and other epigenomic processes (Xing & van der Laan, 2005). Considered together, these technical and computational problems are scientific impediments of remarkable complexity and difficulty, yet molecular biologists and biostatisticians are making steady progress toward tractable solutions to these previously unencountered complexities.

Dilemmas in Bioethics and Health Policy

The bioethical and social policy implications of more rigorous studies of gene-environment interactions are also vast. Wilmoth and colleagues (Wilmoth, Deegan, Lundström, & Horiuchi, 2000) have demonstrated, for example, that contrary to prevailing assumptions, the human life span is not fixed but, in fact, has been slowly advancing for more than a century. Wildner (2000) noted a similar phenomenon in *Drosophila* and suggested that the slowing of mortality among the older age groups of both species may be related to a favorable gene-environment interaction. Maximizing the fit between individual genotypes and the environments that most favor health and well-being could thus have immense consequences not only for the emerging psychopathologies of childhood but for the public health of the world.

Furthermore, a deeper understanding of the genetic sources of vulnerability and of the ways social context can ameliorate or provoke susceptibility may eventually require ethical, democratic societies to move beyond claims of distributive justice as the sole basis for societal obligations to intervene and assist vulnerable children (Halpern & Boyce, *in press*). If current social institutions and settings are shown to play causal roles in harming such children, increasing their risks of mental and physical illness, society may have the strongest kind of ethical obligation: the obligation to change institutions to desist from harm. At a more fundamental level, there are classical as well as emerging ethical perspectives that give special attention to individuals in vulnerable periods of development, in part due to the inability of not yet mature individuals to argue on their own behalf. These developmental vulnerabilities seem to interact with social contextual adversities, increasing serious risks of disorder during periods of especially high social stress (Boyce & Keating, 2004; Keating & Mustard, 1993). I suggest that these ethical considerations serve as a

salient underpinning for the scientific and policy debates that are implied by the scientific observations on vulnerability and resilience that animate this chapter.

Dilemmas Regarding Individual- and Population-Level Interventions

Finally, among the implications of greater knowledge of biology-context interactions is a set of questions surrounding the interventions that would logically follow from such knowledge. On the one hand, one might argue that the genetically grounded, exaggerated sensitivity of certain individuals to ambient environmental adversities should mandate a population-wide reduction in stress exposure and the provision of enhancements to general societal supports. The progressive, federally defined decreases in acceptable environmental lead exposures and blood lead levels in children, for example, were due in part to the discovery of a subset of children with genetically derived special sensitivities to lead effects on heme synthesis pathways (Wetmur, Lehnert, & Desnick, 1991). It was thus the elucidation of a vulnerable subpopulation that prompted a population-wide mandate for decreased exposure.

On the other hand, the identification of genetically vulnerable individuals offers the opportunity to construct surveillance processes and interventions that are specifically targeted to individuals at greatest biological risk for a given category of disease (Khoury, Burke, & Thomson, 2000b). In the field of developmental psychopathology, for example, knowledge of the gene polymorphisms associated with risk for anxiety and affective disorders could potentially lead to school-based interventions capable of preventing entry onto trajectories toward such disorders. In another example, Omenn (2000) pointed out that persons with a genetic trait that decreases the catabolism of nicotine were less likely to be tobacco-dependent, suggesting the possibility of preventive interventions targeting the metabolically at-risk individuals. It is important to note that, as argued by Turkheimer (1998), the establishment of genetic contributions to disease etiology does not necessitate genetic, or even biological, interventions. In Suomi's studies, cited earlier, the provision of expert, highly nurturant foster care for vulnerable young monkeys created dramatically beneficial effects, even though the means of identifying such monkeys involved sophisticated biological assays of stress response. Although adjustments in the environmental component of biology-context interactions may be currently more technically feasible and acceptable, the most recent work of Sapolsky and colleagues (Kaufer et al.,

2004) serves as a harbinger of genetic interventions that could plausibly alter even the most fundamental, molecular aspects of human emotional and behavioral regulation. Whatever the future of gene therapies, the potential for psychosocial and societal intercessions into human adversities could paradoxically be served in unparalleled ways by the study of interactions between biology and context.

Far from a yellow brick road into ascendant knowledge, the path we are now following is rife with new perils and ethical conundrums. Khoury et al. (Khoury, Burke, & Thomson, 2000a) have reviewed comprehensively the scope of such issues that science and human societies must now face, highlighting the dilemmas surrounding privacy and confidentiality, fair use of genetic information, and the prospects for individual and group stigmatization. An outstanding precedent for attending to and addressing such dilemmas is the Ethical, Legal, and Social Implications Program that was established as an integral component of the Human Genome Project (National Human Genome Research Institute, 2005). As new research on gene-environment interactions proceeds, it will be critical for universities and agencies at both national and local levels to follow the Human Genome Project's responsible lead by addressing forthrightly the human and ethical problems that necessarily accompany such research.

CONCLUSION

Despite the difficulties, both philosophical and technical, that will surely attend the continuing and now compelling study of biology-context interaction, it is increasingly clear that such interactions will be among the keys that unlock one of the most ancient and compelling of human mysteries: the etiologies of disease and disorder. Having begun the process of documenting and cataloguing the range of biology-context interactions, it is now time to explore symphonic causation: the patterned, intrinsic regularities in *how* biology and context work together, and what genes and environments *do* in their conjoint elicitation of disease. In seeking to understand the complexity of developmental psychopathology, no problem is more salient and no solution more suffused with potential and hidden rewards.

Subject Index

- Abducent nerve, 77
Abused/neglected children. *See* Childhood abuse/neglect
Accessory nerve, 77
Acetylcholine (ACh), 25, 73, 74, 233–235
Action and awareness, 73–74
Action selection system, 339–340
Active self, 66
Adaptation:
 information-processing model, 593–594
 for mothering, 94
 stress and general adaptation syndrome, 81
 temperament and, 476–478
Adaptive immunity, effector phase, 683
Additive genetic effects, 428
Adolescence, study of developmental psychopathology in, 312–314, 710–735
 arousal, motivation, and affect regulation during puberty and adolescence, 720–724
 neurobiology of affect regulation, 721
 pubertal maturation and affective development, 721–722
 puberty and psychopathology, 722–724
 sleep and arousal at puberty, 722
brain development in adolescence, 716–720
 contextual effects, 718–719
 mammalian species, 717–718
 specific brain regions, 719–720
context and development of psychopathology, 726–733
 community, society, and culture, 732
 family, 729, 730
 media and virtual contexts, 732
 new approaches, 732–733
 peers, 729–730
 romantic relationships, 730
 schools, 730–731
 work, 731–732
development of regulatory competence, 724–726
future directions, 733–735
general observations, 712–714
neuroscience perspective on cognitive development, 724–725
prefrontal cortex, 312–314, 725–726
self-regulation, and psychopathology, 714–716
Adoption, 106, 113
Adoption design, 428
Adrenal gland, 73, 537
Adrenaline, 73
Adrenal secretion, 543–544
Adrenocorticotropin hormone (ACTH), 82–83, 84, 536, 537, 549, 550, 661, 663
Adversity, early:
 allostatic load, 590–611
 false belief understanding, 597–598
 future directions, research on influence on brain development, 614–615
 language development, 596–597
 perceptual and representational systems, 595–596
 positive outcome in the context of; concept of resilience, 598 (*see also* Resilience)
Affective disorders:
 abused/neglected children at greater risk for, 334
 future directions, 243–244
 genetics and resilience, 46–47
Affectivity:
 positive, 471–472
 Schizophrenia, 220
 temperament, 471–472
Affect regulation:
 neurobiology, 721
 puberty and adolescence, and arousal/motivation, 720–724
Affiliation, 474–475, 766–773, 783–788
 agentic extraversion and, 766–773, 783
 agreeableness, 474–475
 nonaffective constraint, 785–787
 separation anxiety and, 783–785
 temperament, 474–475
Affiliative reward, 769–772, 788
Agentic extraversion:
 and affiliation, 766–773, 785–787
 and aggression, 785–787
 and anxiety, 783, 785–787
 and nonaffective constraint, 785–787
Aggression:
 affiliation and, 785–787
 agentic extraversion and, 785–787
 anger/irritability and, 474
 approach, frustration, and, 476–477
 fear, over-control, and, 477–478
Aging, allostatic load and, 589
Agoraphobia, 481
Ainsworth's Strange Situation, 104
Alarm, resistance, and exhaustion phases, 81
Alcohol-Related Neurodevelopmental Disorder (ARND), 146
Alcohol Spectrum Disorders, Fetal, 146–147, 751
Alert/alerting:
 ADHD, 489–490
 function, 475
 temperament, 489–490
Allele, 441
Alloparenting, 556
Allostasis:
 adaptation and, 81
 homeostasis versus, 581
 in integration of autonomic and emotional regulations, 78–79
 literal definition, 79
Allostatic balance, 70
Allostatic load, 535, 578–616
 absolute versus relative stressors, 580
 acute versus chronic stress, 580–581
 bottom-up effects and, 583–588
 in children:
 externalized behaviors/conduct in children, 598–607
 validation of, 606–607
 chronology of the process, 586–587
 conduct disorder and, 604–606
 cholesterol, 602–603
 cortisol, 600–602
 cortisol and immune function, 605–606
 dehydroepiandrosterone and conduct disorder (DHEA and its sulfate DHEAS), 602
 general cognitive/brain dysfunctions, 599–600
 genetic influences on the hypothalamic-pituitary-adrenal axis—results from twin studies, 607–611
 heart rate and conduct disorder, 603–604
 immune function and conduct disorder, 604
 low cortisol and high sulfated dehydroepiandrosterone, 605
 low cortisol and low heart rate, 605
 waist-hip ratio and conduct disorder, 603
 early adversity and development of, 590–611

864 Subject Index

- Allostatic load (*Continued*)
effects on the brain, 584–586
eustress versus distress, 580
examples:
 brain system, 582
 cardiovascular system, 582
 immune system, 582
 metabolic system, 582
future directions, 611–615
glucocorticoids and, 583
historical background, 578–579
hypothalamic-pituitary-adrenal axis, 579
model, 578–590
primary effects, 583, 587–588
primary mediators, 587
schematic representation, 583
secondary outcomes, 583, 587, 588
stages of, and physiological and clinical markers used to assess degree, 587
stress, stressor, stress response, eustress, and distress, 579–581
tertiary outcomes, 583, 587, 588
top-down processing, 582–583
top-down processing meeting bottom-up effects, 584–588
- Alphabet, cognitive, 786
- Alzheimer's disease, 339, 450
- Ambivalent social attachment style, 784–785
- Amino acids, 74
- Amphoteronomics, 70, 106
- Amygdala:
 differentiation, 91
 emotionally stimulated learning and, 225–226
 extended, 776
 in LHPA illustration, 537
 limbic mechanisms and varieties of stress response, 80, 83
 role in pathophysiology of mental disorders, 240–242
- Analysis levels. *See* Levels of analysis
- Anatomic brain imaging studies (children/adolescents), 127–180
atypical brain development, 139–176, 203–207
 affective disorders, 171–172
 attention-deficit/hyperactivity disorder (ADHD), 157–163
 autistic disorder, 150–156
 bipolar disorder, 172–173
 childhood-onset Schizophrenia, 166–171
 depression, 173–176
 disorders associated with known genetic or environmental factors, 140–149
 disorders with increased onset at adolescence, 166–176
 dyslexia, 156–157
 fetal alcohol syndrome, 146–147
 fragile X syndrome, 141–144
 model delineating different levels of analysis, 140
 neuropsychiatric disorders commonly first diagnosed in childhood, 150–165
 obsessive-compulsive disorder (OCD), 163–166
 PTSD, 147–149
 Rett syndrome, 144–146
evolution of neuroimaging techniques, 128–129
future directions, 177–180
methodology, 128–132
parameters to consider in structural pediatric neuroimaging studies, 129–132
typical development, 132–139, 202–205
 cortical gray matter, 135
 cross-sectional versus longitudinal study design, 131–132
 diffusion tensor imaging (DTI), 130
 fetal and perinatal brain development, 133–134
 image acquisition, 129
 image analysis, 130
 imaging studies in older children and adolescents, 134
 key steps in early brain development, 132–133
 selection of control populations, 131
 selection of patient populations, 130–131
 sequence of events in brain maturation (a diagram), 132
 studies, 133–139
 subcortical gray matter, 135–137
 T1 and T2 relaxometry and magnetization transfer imaging, 129–130
 total cerebral volume, 134–135
 ventricles, 135
 white matter, 137–139
- Anemia, and cognitive performance, 272
- Anger/irritability and aggressive behavior, 474
- Anorexia, 689
- Anterior cingulate, 80, 224–225, 294
- Anterior pituitary, 544, 545
- Anterior visceral endoderm (AVE), 87
- Antibodies/immunoglobulins, 682–683
- Anticortisol, 536
- Antidepressants, 49
- Antisocial Personality Disorder (APD), 265, 599–600
- Anxiety:
 affiliation and, 783–787
 agentic extraversion and, 783, 785–787
 aggression and, 785–787
 comorbidity with depression, 481
 disorders, 552–554
 cytokines, 691
 genetic studies, 481
 neuroticism, 773–779
 versus fear (distinct behavioral systems), 773–774
 neurobiology of, 774–779
 nonaffective constraint, 785–787
 orienting, 490
 separation, 783–785
 temperament, 490
- Appetitive systems, 505–506, 507
- Arousal, measures of physiological, 394–409
 cortisol, 399–404
 cortisol and developmental psychopathology, 400–404
 future directions, 404
 methodology, 399–400
 electroencephalogram, 404–409
 future directions, 408–409
 methodology, 405–406
 study of developmental psychopathology, 406–408
 measures of parasympathetic activity and reactivity, 396–399
 autonomic reactivity and developmental psychopathology, 397–399
 future directions in use of autonomic nervous system measures, 399
 heart rate variable (vagal tone), 396–397
 measures of sympathetic activity and reactivity, 395–396
 electrodermal activity, 395–396
 heart rate, 395
 systolic time intervals, 395
- Arousal/motivation system, 339–340, 720–724
- Aspartate, 94
- Asperger's Disorder, 342–343
- Association, 441
- Associative learning, 769
- Asymmetric divisions, 72
- Asymmetry, EEG, 37–38, 409–411, 473
- Attachment:
 collaborative play and companionship in infancy, 66, 70
 learning and, 103–106
 shared experiences in infancy, 103–106
 theory, and normative variations in caregiving, 559
 therapy based on, for neglected or abused children and parents who foster or adopt them, 113
- Attention:
 Autism, 346–347
 development and, 488–492
 executive function, 475
 psychopathology and, 486–492
 regulation of, 512–513
 selective; to threatening information in maltreated children, 595
- Attentional networks, 475–476
 assessing individual differences in, 487–488
 brain areas and neuromodulators involved in, 475
 regulatory functions of, 476
- Attention-deficit/hyperactivity disorder (ADHD):
 aggression, 477
 appetitive systems, overreactive, and symptoms related to, 507
 corpus callosum, 749, 750–751
 dopamine, 448–449, 509, 521
 genetics, 101, 437, 439, 443, 444–445, 449, 452–454
 heart rate and cortisol levels, versus ODD, 605
 measures of physiological arousal, 394, 398
 neuropsychological perspectives, 333, 336, 352
 prepulse inhibition and the study of developmental psychopathology, 393–394
 specificity in association and linkage between dopamine genes and ADHD, 448–449
 stress and early psychopathology, 101
 structural neuroimaging, 157–163
 temperament/attention and, 479
- Attention Network Test (ANT), 487–488
- Attunement, 67

- Atypical brain development, anatomic imaging studies of, 139–176
 disorders associated with known genetic or environmental factors, 140–149
 fetal alcohol syndrome, 146–147
 fragile X syndrome, 141–144
 PTSD, 147–149
 Rett syndrome, 144–146
 disorders with increased onset at adolescence, 166–176
 affective disorders, 171–172
 bipolar disorder, 172–173
 childhood-onset Schizophrenia, 166–171
 depression, 173–176
 model delineating different levels of analysis, 140
 neuropsychiatric disorders commonly first diagnosed in childhood, 150–165
 Attention-Deficit/Hyperactivity Disorder (ADHD), 157–163
 autistic disorder, 150–156
 dyslexia, 156–157
 Obsessive-Compulsive Disorder (OCD), 163–166
- Auditory nerve, 77
- Aunting, 556
- Autism:
 basal ganglia, 154
 brain mechanisms, 345–346
 brain size, 16, 151–153
 cerebellum, 155
 corpus callosum, 154, 749–750
 studies in callosal area and shape, 750
 studies on callosal tissue integrity, 750
 empirical research review, 342–355
 Level 1 analysis, 344–345
 Level 2 analysis, 345–346
 Level 3 analysis, 346–354
 Level 4 analysis, 342–344
 epidemiology, 343–344
 etiology—genes, environmental factors, and interactions, 344–345
 experience and brain development, 14–17
 gastrointestinal (GI) disturbances, 344–345
 memory, 347–348
 neuroimaging studies, 150–156
 neuropsychology, 346–354
 orienting, 490–491
 overview table, structural neuroimaging studies, 152–153
 regressive, 345
 symptoms, diagnostic definitions, 342–344
 temperament, 490–491
 temporal lobe structures, 154–155
 white and gray matter, 153–154, 749–750
- Autobiographical memory, 643–647
- Autonomic nervous system (ANS), 72, 73
- Autonomic reactivity and developmental psychopathology, 397–399
- Autonomics, 70
- Autonomy in regulatory system of the fetus and coregulation before birth, 99–100
- Autopoiesis, 87
- Avoidant-anxious social attachment style, 785
- BDNF (brain-derived neurotrophic factor), 661
- Bed nucleus of the stria terminalis (BNST), 776, 777
- Behavior:
 cytokines:
 and developmental plasticity of biological basis of, 693–695
 internalizing problem behavior and, 690–691
 methods to study behavioral effects, 691–693
 environmental enrichment and, 30–31
 multidimensional biobehavioral profiles, 383–384
 neural plasticity and, 32–33
 physiology and, 382–385
 preverbal, 384
- Behavioral facilitation system (BFS), 472
- Behavioral genetics. *See* Genetics

872 Subject Index

- Neuropsychological perspectives on developmental psychopathology
(Continued)
neuropsychological domains relevant to developmental psychopathology, 339–341
 lesion models, 340–341
 Luria's model, 339–340
neuropsychology of specific developmental psychopathologies, 341–342
neuroscientific perspective, 333–341
posttraumatic stress disorder, 355–366
 symptom level, one major concern of, 336
- Neuroses, 658
- Neuroticism, 773–779. *See also* Anxiety
- Neurotransmitters, 73–74, 232–236
 acetylcholine (ACh), 25, 73, 74, 233–235
 action and awareness, 73–74
 amino acids, 74
 dopamine (DA), 74, 235–236 (*see also* Dopamine)
 extrinsic, 233–236
 gamma-aminobutyric acid (GABA), 19, 74, 94, 233, 539
 glutamate (GLU), 74, 94, 233
 intrinsic, 232–233
 LHPA axis and, 539
 monoamines, 46, 74, 238, 546
 neuropeptides, 74
 noradrenaline (NA), 73, 74, 91, 94
 norepinephrine, 73, 235, 540
 PTSD and, 360
 serotonin or 5-hydroxytryptamine (5HT), 74, 91, 92, 235, 540, 781, 786–787
 types, 74
- New York Longitudinal Study (NYLS), 468–470
- Nitrous oxide (NO), 74
- NMDA receptor activation, 12
- Nonshared environment (defined), 428
- Noradrenaline, 73, 74, 91, 94
- Noradrenergic neurons, 91
- Norepinephrine, 73, 235, 540
- Nucleus accumbens, 506
- Nucleus paragigantocellularis, 79
- Nucleus of the tractus solitarius (NTS), 73, 537, 539
- Nutritional deficiencies in brain development, 259–284
 basic principles, 261–262
 definitions of terms, 261
 future directions, 280–284
 human studies of cognitive development, 268–275
 iodine, 279
 iron, 279
 neurobiology, 275–278
 overview, 262
 studies on psychopathology, 262–268
 undernutrition or malnutrition, 261
 zinc, 279–280
- Object retrieval task, 309
- Obsessive-compulsive disorder (OCD), 163–166
 autobiographical memory, 644
 behavioral genetics, 438
 corpus callosum, 749
 cytokines, 691
 executive function, 352
 overview table, structural neuroimaging studies, 164
 structural neuroimaging, 163–165
 treatment strategies, 334
- Oculomotor nerve, 77
- Oculomotor nucleus, 91
- Olfactory memory tasks, 11
- Olfactory nerve, 77
- Ontogeny, immune system, 681–682
- Oppositional defiant disorder (ODD), 402, 479, 550, 605
- Optic nerve, 77
- Orbital network, 504
- Organic/functional disorders, distinction, 332
- Orient/orienting:
 anxiety and depression, 490
 Autism, 490–491
 function, 475
 temperament, 490–491
- Overanxious Disorder, 507
- PAG (periaqueductal gray), 503–504, 507, 513, 775

- Parasympathetic nervous system (PNS), 72, 73, 76–78
- Parenting:
 additive effects of temperament and, 484–485
 interactive effects of temperament and, 485–486
- Parity, 613–614
- Pavlovian associative learning, 769
- Peabody Picture Vocabulary Test-Revised (PPVT-R), 41
- Peers, as positive/negative influences on adolescent development, 729–730
- PEM. *See* Positive emotionality (PEM); Protein energy malnutrition (PEM)
- Perception/memory system, 339–340
- Peripheral arousal, regulation of, 510–511
- Peripheral catecholaminergic system, 545
- Personality:
 constitution and the environment as determinants of vulnerability and, 218–219
 motivational systems and, 506–507
- Schizophrenia and, 219–222
 affectivity, 220
 logical processing, 221–222
 motivation, 221
 selective attention, 220–221
 sociability, 221
- Personality disturbance, 762–789
 future directions, 787–788
 interactive nature of emotional traits and constraint, 783–789
 affiliation and separation anxiety, 783–785
 agentic extraversion, anxiety, aggression, affiliation and nonaffective constraint, 785–787
 agentic extraversion and affiliation, 783
 agentic extraversion and anxiety, 783
 multidimensional model, 788
 problem of modeling nonentities, 764–766
- Personality traits, neurobehavioral systems underlying, 766–782
 agentic extraversion and affiliation, 766–773
 anxiety or neuroticism, 773–779
 conceptualizing individual differences, 781–782
 neurobiology of incentive motivation and affiliative reward, 769–772
 nonaffective constraint or impulsivity, 779–782
 delimiting heterogeneity of impulsivity/constraint, 779
 neurobiology of nonaffective constraint, 781
- studies:
 personality questionnaire traits used in 11 studies, corresponding to numbered trait abbreviations in plotting, 789, 795–796
 plotting of loadings (in 11 studies), 780
 trait complexities related to interpersonal behavior, 766–767
- Pervasive developmental disorders (PDDs), 342. *See also* Autism
 Asperger's disorder, 342–343
 Childhood disintegrative disorder, 342, 343
 Not Otherwise Specified (PDD-NOS), 342, 343
 Rett syndrome/disorder, 144–146, 342, 343
- PFC. *See* Prefrontal cortex (PFC)
- Phenotypic traits, 436
- Phenotypic variability, 336–337
- Phenylketonuria (PKU):
 chronic deviation in prefrontal dopamine activity, 319–320
 nutritional factors in brain development, 259
- Phlegmatic person, 467
- Phonological processing system, 341
- Physical growth, 545
- Physical Health, trauma and, 667–669
- Physiological measures. *See* Psychophysiological approach
- Pituitary, 537. *See also* Limbic-hypothalamic-pituitary-adrenocortical (LHPA) system
 anterior pituitary, 544, 545
- Placenta, 87, 107
- Plasticity in brain development, 201. *See also* Neural plasticity
- Pluralism, explanatory/methodological, 3
- Polygenic, 428
- Polymerase Chain Reaction (PCR), 45–46
- Polymorphism, 441
- POMC gene expression, 536
- Population stratification (defined), 441
- Positive emotionality (PEM), 477
- Positive incentive motivation, 768
- Posttraumatic stress disorder (PTSD):
 amygdala function in, 666
 anterior cingulate cortex, 83
 caregiving and LPHA activity, 559, 561
 corpus callosum, 749
 cortisol, 402, 403

- early experience and gene expression interplay, 46
 fear, 79, 637
 hippocampus, 45
 historical, 658
 imaging studies, 147–149
 memory, 637, 644, 646
 mother–infant system, 105
 multiple-levels-of-analysis perspective, 658, 660, 662, 663, 664, 665, 668
 neural development, effect of stress/trauma on, 634
 neurobiology of anxiety, 778
 neuropsychological perspectives, 339, 355–366
 attention and executive function, 363
 brain mechanisms, 359–361
 environment and transactions, 358–359
 epidemiology, 357
 etiology—genes, environmental factors, and interactions, 357–359
 genetics, 357–358
 HPA axis, 359–360
 Level 1 analysis, 357–359
 Level 2 analysis, 359–361
 Level 3 analysis, 361–366
 Level 4 analysis, 356–357
 limbic system, 360
 memory, 362–363
 neuropsychology, 361–366
 neurotransmitters, 360
 social cognition, 363–364
 structural and functional imaging studies, 360–361
 symptoms, diagnostic definitions, and epidemiology, 356–357
 prepulse inhibition and study of developmental psychopathology, 393
 replications of findings from functional imaging in, 665
 startle reflex, 36–37
 stress effects on brain after birth, 103
 Vietnam war, 614–616
- Potentiation:
 long-term (LTP), 28–29, 278
 symphonic causation nosology, 805, 806
- Prefrontal cortex (PFC), 216–250, 292–324. *See also* Corticolimbic system
 adolescence to young adulthood, 312–314, 720
 cognition–emotion interactions and development of the ventromedial
 prefrontal cortex, 315–317
 cognitive neuroscience and, 292–324
 computerized assessments of frontal lobe function, 311–312
 constitution and the environment as determinants of personality and
 vulnerability, 218–219
 defined, 293–294
 developmental implications, 304
 dimensional view of functional development of, 307–317
 foresightful motives and sociability, 97–98
 function, 297–307
 future directions, 242–248, 321–323
 historical perspectives on, and behavioral regulation, 294–296
 implications, 315
 individual differences and vulnerability to pathology, 317–321
 phenylketonuria, 319–320
 Schizophrenia, 318–319
 substance abuse, 320–321
 infancy, 307–309
 maturation of distinct lateral prefrontal cortex regions, 314–315
 neurocognitive measures, 308
 preschool and middle childhood, 309–312
 regulatory competence, 725–726
 sources of individual variation in structure, 297–304
 genetics and neurochemical variations, 301–304
 metabolism, 300
 neurogenesis and cellular migration, 298
 synaptic development, 299–300
 synaptic pruning, 299
 synaptogenesis, 298–299
 volumetric changes, myelination, and white matter integrity,
 300–301
- Prefrontal lobotomies, 296
- Prenatal period:
 allostatic load, 611–612
 embryo development:
 early embryo (0 to 30 days), 89–90
 illustration, 88
 late embryo (30 to 60 days), 90–91
 vital integration with the mother’s body and development of human form,
 89–91
- fetal development:
 early fetus (60 to 100 days), 92–93
 fetus and mother, both in adaptive states of calm inwardness, interaction
 with muscular activity, 84
 last trimester (200 to 280 days): preparation for birth, 93–94
 midfetus (100 to 200 days), 93
 placenta, 87
 preparing the body and brain for intelligent activities and a sociable life,
 91–94
 hormonal milieu of mother, 611–614
 stages and adaptations for interdependency with the mother, 86–89
- Prepulse inhibition, 391–394
 future directions in use of, 394
 startle methodology, 392–393
 study of developmental psychopathology and, 393–394
- Preschool Behavior Questionnaire, 478
- Primary maternal preoccupation, 100
- Primary neurulation, 132
- Probabilistic epigenesis:
 deterministic versus, 199–200
 framework, 10–11
- Prodrome, 166
- Proliferation, 132
- Prosencephalic development, 132
- Protection (symphonic causation nosology), 806, 807
- Protein energy malnutrition (PEM), 261, 269, 278
- Protest, 557
- Protoconversation between mother and infant, 107
- Protocortex model, 6
- Protomap hypothesis, 6
- Psychophysiological approach, 381–416
 future directions, 414–416
 measures of motivation and emotion, 409–414
 affective modulation of the startle reflex, 411–414
 electroencephalogram asymmetry, 409–411
 measures of physiological arousal, 394–409
 cortisol, 399–404
 parasympathetic activity and reactivity, 396–399
 sympathetic activity and reactivity, 395–396
 physiological measures of cognitive processing, 386–394
 event-related potentials, 386–391
 prepulse inhibition, 391–394
 questions addressed by, 385–386
 strengths, 382–385
 assessing function through timing of physiological change, 383
 providing insight into the behavior of preverbal and young children, 384
 providing multidimensional biobehavioral profiles, 383–384
 understanding dissociations between physiology and behavior, 384–385
 understanding physiology-behavioral connection, 382–383
- Psychosurgery (term coined), 296
